## ABSTRACT

To improve nonparametric estimates of lifetime distributions, we propose using the increasing odds rate (IOR) model as an alternative to other popular, but more restrictive, ‘adverse ageing’ models, such as the increasing hazard rate one. This extends the scope of applicability of some methods for statistical inference under order restrictions, since the IOR model is compatible with heavy-tailed and bathtub distributions. We study a strongly uniformly consistent estimator of the cumulative distribution function of interest under the IOR constraint. Numerical evidence shows that this estimator often outperforms the classic empirical distribution function when the underlying model does belong to the IOR family. We also study two different tests to detect deviations from the IOR property and establish their consistency. The performance of these tests is also evaluated through simulations.

## 1. Introduction

In statistics, the problem of estimating a cumulative distribution function (CDF)  $F$ , often depends on any prior information on  $F$ . This is, for example, the idea that gives rise to parametric inference. On the other hand, no information on  $F$  leads to the most basic nonparametric estimator of  $F$ , namely, the empirical CDF  $\mathbb{F}_n$ . The approach based on shape-restricted inference represents an intermediate case, in which it is assumed that  $F$  belongs to some important, and as broad as possible, nonparametric family of distributions, satisfying some shape constraints. It is obvious that, using a stronger shape constraint, one may expect a larger estimation improvement upon  $\mathbb{F}_n$ , but, on the other hand, less applicability and higher risk, if the constraint is false. Thus, these shape restrictions should be chosen to reasonably conform to the data, and validated through statistical testing.

In reliability and survival analysis, one is generally interested in random lifetimes, so it is typically assumed that distributions may exhibit ‘adverse ageing’, vaguely meaning that ageing has a negative effect on lifetime (Marshall and Olkin 2007). The classic (but not unique) way of translating this intuitive notion into a mathematical language is assuming that  $F$  has an *increasing hazard rate* (IHR). For this reason, nonparametric inference

for IHR distributions represents an extremely relevant case, which has been studied by Grenander (1956), Marshall and Proschan (1965) or Prakasa Rao (1970), among many other authors. However, the IHR assumption is sometimes considered to be too strong. For example, it is not compatible with heavy-tailed (as it requires the existence of all moments) and *bathtub* distributions, namely, distributions that exhibit a U-shaped hazard rate (Marshall and Olkin 2007). The solution to this problem may be using a weaker shape restriction, which is still coherent with the ‘adverse ageing’ notion. For example, Wang (1987), Rojo and Samaniego (1994) or El Barmi et al. (2021) estimate distributions which exhibit an IHR, but only on average (IHRA). Although the IHRA class contains the IHR class, this family still requires the existence of all moments and does not contain any bathtub model. Therefore, the problem of estimating  $F$  within a weaker ‘adverse ageing’ setting, compatible with heavy-tailed and bathtub distributions, is particularly interesting.

In a recent paper, Lando et al. (2022a) proposed an ageing class that is based on the monotonicity of the *odds rate* (OR), instead of the hazard rate. In fact, ageing classes are typically defined in terms of some suitable stochastic ordering constraint, taking the exponential distribution as the classic benchmark for ‘no ageing’. This is due to the well-known ‘lack of memory’ property. However, a wider family than the IHR may be constructed by replacing the exponential with a different reference distribution, providing an alternative interpretation of ‘no ageing’. In particular, as discussed in Lando et al. (2022a), the log-logistic distribution (with shape parameter equal to 1), hereafter referred to as LL(1), may be a suitable benchmark, as it satisfies a ‘multiplicative lack of memory’ property (Galambo and Kotz 2006), and it is the only distribution such that the *odds of failure* by time  $x$ , that is the probability of failure over survival at  $x$ , has a constant growth rate with respect to time. Moreover, unlike the exponential distribution, the LL(1) distribution has an infinite expectation, which is also more coherent with a literal intuitive translation of the ‘no ageing’ concept. The family of distributions that are dominated by the LL(1) with respect to the *convex transform order* of Van Zwet (1964) is called the *increasing odds rate* (IOR) family. Besides having some interesting properties, the IOR class has a wide range of applicability: it does not require the existence of moments, it contains all IHR distributions, plus some important heavy-tailed and bathtub ones (see Section 2.1 of Lando et al. (2022a)). Accordingly, the objective of this paper is to obtain an estimator of  $F$  that satisfies the IOR assumption, hence improving upon  $\mathbb{F}_n$  under weak conditions. In Section 3, we construct such an estimator, denoted as  $\widetilde{\mathbb{F}}_n$ , using similar methods as those discussed in the books of Barlow et al. (1971) or Robertson et al. (1988).  $\widetilde{\mathbb{F}}_n$  is strongly uniformly consistent, and simulations show that it is generally more accurate than  $\mathbb{F}_n$ , provided that the IOR assumption holds. On the other hand, it is clear that the method does not work properly when the IOR assumption is false, therefore it is important to decide, based on statistical testing, whether the data support the IOR assumption or not. In Section 4, we obtain two different nonparametric tests to detect violations of the IOR property. We study the properties of these tests, establish their consistency, and compare their performances simulating the values of the power function under some critical alternatives.

## 2. The IOR property

Let us begin with some preliminary notations. Throughout this paper, ‘increasing’ signifies ‘non-decreasing’ and ‘decreasing’ signifies ‘non-increasing’. We define the *greatest convex*

*minorant* (GCM) of a function  $g$ , denoted as  $g_{cx}$ , as the largest convex function that does not exceed  $g$ . Similarly, the *least concave majorant* (LCM) of  $g$ , denoted as  $g_{cv}$ , is the smallest concave function which is larger than or equal to  $g$ . Throughout this paper,  $X$  denotes a random variable with an absolutely continuous CDF  $F$  and probability density function (PDF)  $f$ . Moreover, for the sake of simplicity, any map  $\phi$  which depends on a CDF  $F$ , will be denoted as  $\phi_F$  or just  $\phi$ , whenever it is clear from the context.

We will now recall the definition and properties of the IOR family. The reader is referred to Lando et al. (2022a) for a more detailed discussion.

Let us denote with  $L(x) = \frac{x}{1+x}$ ,  $x > 0$ , the CDF of the LL(1) distribution. The function

$$\Lambda_F(x) = L^{-1} \circ F(x) = \frac{F(x)}{1 - F(x)}$$

defines the odds of failure by time  $x$ . The function  $\Lambda_F$  is obviously increasing, so it is natural to get interested in its growth rate. In fact, one may expect that  $F$  exhibits ‘no ageing’, in some sense, when the *odds rate* of  $F$ , defined as

$$\lambda_F(x) = \Lambda'_F(x) = \frac{f(x)}{(1 - F(x))^2}, \tag{1}$$

is constant. Similarly, an increase of  $\lambda$  means that the probability of failure over survival is accelerating with respect to time, suggesting an ‘adverse ageing’ scenario. Therefore, we are interested in distributions with an increasing behaviour of  $\lambda$ , or, equivalently, with a convex odds function  $\Lambda$ . This family, formally  $\mathcal{F}_{IOR} = \{F : \Lambda_F \text{ is convex}\}$ , is referred to as the IOR class.

Note that the convexity of  $\Lambda$  does not imply the existence of a density. Indeed, this convexity allows for a single point mass of  $F$  at the right endpoint of the support. However, for simplicity of the presentation, we shall assume the existence of a PDF.

It is easy to see that the IOR class contains the well-known IHR class, which may be characterised as  $\{F : -\ln(1 - F) \text{ is convex}\}$ . Indeed, if the HR, defined as  $(-\ln(1 - F))' = \frac{f}{1-F}$ , is increasing, then the OR is increasing as well, taking into account (1). These two classes may be equivalently defined in terms of the convex transform order, requiring convexity of  $G^{-1} \circ F$ , where  $G$  is some suitable (and fixed) reference CDF. In general,  $G$  dominates  $F$  in the convex transform order, denoted as  $G \geq_c F$ , if  $G^{-1} \circ F$  is convex (Shaked and Shanthikumar 2007). The IHR class is obtained by choosing  $G(x) = \mathcal{E}(x) = 1 - e^{-x}$ ,  $x > 0$ , namely, the unit exponential distribution. The main reason for choosing  $\mathcal{E}$  as a benchmark is that it satisfies the ‘lack of memory’ property. Likewise, for  $G = L$ , we obtain the IOR class, and it is also easy to see that, if  $X \sim L$ , then the shifted random variable  $X + 1$  satisfies the ‘multiplicative lack of memory’ property, that is,  $P(X + 1 > ab | X + 1 > a) = P(X + 1 > b)$ , for every  $a, b > 1$  (Galambos and Kotz 2006). Bear in mind that ageing notions are typically location and scale independent, in particular,  $X$  and  $\sigma X + \mu$  are equivalent in terms of the convex transform order. In this regard, we may refer to the LL(1) location-scale family, determined by the CDF  $L$  up to location and scale transformations.

We now discuss the applicability of the IOR model. First, note that the IOR class may contain bathtub distributions, characterised by a ‘decreasing then increasing’ behaviour of the HR, and are commonly employed in survival analysis and reliability (see, for

example, Marshall and Olkin (2007), or Glaser (1980)). For instance, under some conditions on the parameters, the bathtub distributions defined by Topp and Leone (1955), Hjorth (1980), Schäbe (1994) or Haupt and Schäbe (1997) are IOR. This class contains also many heavy-tailed distributions, such as the log-logistic, the Pareto, the Burr XII, the Fréchet, the Student's  $t$  (with shape parameter(s) larger than or equal to 1), the lognormal (under some conditions) and the Cauchy distributions. It is not possible to establish inclusion relations between the IOR class and other relevant classes which contain the IHR class, such as the IHRA and the DMRL families (Marshall and Olkin 2007). However, like the IHR, these latter classes require the existence of all moments, therefore they cannot be used as shape constraints to estimate heavy-tailed distributions, which is one of the main advantages of the IOR model. This discussion motivates us to study non-parametric inference on lifetime distributions using the IOR constraint, instead of the IHR one.

### 3. An IOR estimator

Since we are interested in random lifetimes, hereafter we will focus on the case in which the distribution of interest  $F$  has support included in the interval  $[0, \infty)$ . Given an ordered sample  $X_{(1)}, \dots, X_{(n)}$  from  $F$ , the empirical CDF is defined as  $\mathbb{F}_n(x) = \frac{1}{n} \sum_{i=1}^n \mathbf{1}_{X_{(i)} \leq x}$ , where  $\mathbf{1}_A$  is the indicator of the event  $A$ . A realisation of the random process  $\mathbb{F}_n$  will be denoted with  $F_n$ . The empirical CDF represents the most natural way of estimating  $F$  without any prior information, as it satisfies several important properties, in particular, the Glivenko–Cantelli theorem establishes strong and uniform convergence of  $\mathbb{F}_n$  to  $F$ . Assume that  $F \in \mathcal{F}_{IOR}$ : we are interested in determining an estimator, say  $\tilde{\mathbb{F}}_n$ , such that  $\tilde{\mathbb{F}}_n \in \mathcal{F}_{IOR}$  and  $\tilde{\mathbb{F}}_n$  converges strongly and uniformly to  $F$ . A first intuitive solution would be estimating  $\Lambda_F$  using its empirical counterpart  $\Lambda_{\mathbb{F}_n} = L^{-1} \circ \mathbb{F}_n = \frac{\mathbb{F}_n}{1 - \mathbb{F}_n}$  (note that  $\Lambda_{\mathbb{F}_n}(X_{(i)}) = \frac{i}{n-i}$ ) and then estimate  $F$  using  $L \circ (\Lambda_{\mathbb{F}_n})_{cx}$ . However, the function  $L^{-1}(p) = \frac{p}{1-p}$  is unbounded in  $[0, 1)$ , accordingly, for every sample size,  $\sup_x |\Lambda_{\mathbb{F}_n}(x) - \Lambda(x)| = \infty$ , and the corresponding IOR estimator defined earlier would not have the desired property. This issue may be solved using a truncated version of  $\Lambda_{\mathbb{F}_n}$ , say  $\Lambda_{\mathbb{F}_n}^\nu = \Lambda_{\mathbb{F}_n}|_{S_\nu}$ , where  $S_\nu = \{x : F(x) \leq 1 - \nu\}$ , for some arbitrarily small  $\nu > 0$ , and  $h|_A$  is the restriction of a function  $h$  to the set  $A$ . Accordingly, one may estimate  $F$  via  $L \circ (\Lambda_{\mathbb{F}_n}^\nu)_{cx}$ . In this case, the problem of consistency may be easily addressed, but just restricted to  $S_\nu$ . Therefore, we will consider a somewhat more involved approach.

For some given CDF  $F \in \mathcal{F}_{IOR}$ , let us define the following integral transform

$$T_F^{-1}(p) = Z_F \circ F^{-1}(p) = \int_0^{F^{-1}(p)} (1 - F(x))^2 dx, \quad p \in [0, 1],$$

where  $Z_F(t) = \int_0^t (1 - F(x))^2 dx$ , and the corresponding scale-free version  $\bar{T}_F^{-1}(p) = \frac{T_F^{-1}(p)}{T_F^{-1}(1)}$ . We shall focus on distributions such that  $T_F^{-1}(1) = \int_0^\infty (1 - F(x))^2 dx < \infty$ . In particular,  $T^{-1}(1) < \infty$  if  $1 - F$  is integrable, that is, if  $F$  has finite mean, because  $\int_0^\infty (1 - F(x))^2 dx \leq \int_0^\infty (1 - F(x)) dx = \mathbb{E}(X)$ . However, the existence of the mean is not necessary: for example, for the CDF  $L$  we have  $T_L^{-1}(1) = 1$ , although  $L$  has infinite mean. The

function  $T^{-1}$  belongs to the family of *generalized total time on test* transforms, which has been studied by Barlow and Van Zwet (1969). Note also that the inverse of  $T_F^{-1}$ , namely  $T_F = F \circ Z_F^{-1}$ , is a CDF with support  $[0, T_F^{-1}(1)]$ .

It can be seen that

$$(T^{-1})'(p) = Z' \circ F^{-1}(p)(F^{-1})'(p) = \frac{(1 - F \circ F^{-1}(p))^2}{f \circ F^{-1}(p)}, \tag{2}$$

so that  $T^{-1}$  is concave, or, equivalently,  $T$  is convex, if and only if  $\frac{f(x)}{(1-F(x))^2}$  is increasing, that is,  $F$  is IOR. Note that  $T^{-1}$  is the identity function if and only if  $F$  is an LL(1) distribution.

For  $k = 1, \dots, n$ , the empirical counterpart of  $T_F^{-1}(\frac{k}{n})$  is

$$T_{\mathbb{F}_n}^{-1}\left(\frac{k}{n}\right) = \int_0^{X_{(k)}} (1 - \mathbb{F}_n(t))^2 dt = \frac{1}{n^2} \left( \sum_{i=1}^{k-1} (2n - 2i + 1)X_{(i)} + (n - k + 1)^2 X_{(k)} \right),$$

where, in particular,  $X_{(0)} := 0$ ,  $T_{\mathbb{F}_n}^{-1}(0) := 0$ , and  $T_{\mathbb{F}_n}^{-1}(1) = \frac{1}{n^2} \sum_{i=1}^n (2n - 2i + 1)X_{(i)}$ . Note that  $T_{\mathbb{F}_n}^{-1}(\frac{k}{n})$  can also be expressed as

$$T_{\mathbb{F}_n}^{-1}\left(\frac{k}{n}\right) = \sum_{j=1}^k \left( \frac{n - j + 1}{n} \right)^2 (X_{(j)} - X_{(j-1)}).$$

For general  $p \in [0, 1]$ ,  $T_{\mathbb{F}_n}^{-1}(p)$  is defined, by linear interpolation, as the piecewise linear function joining the points  $(\frac{k-1}{n}, T_{\mathbb{F}_n}^{-1}(\frac{k-1}{n}))$  and  $(\frac{k}{n}, T_{\mathbb{F}_n}^{-1}(\frac{k}{n}))$ ,  $k = 1, \dots, n$ . Similarly, the estimator of  $\bar{T}^{-1}$  is  $\bar{T}_{\mathbb{F}_n}^{-1} = \frac{T_{\mathbb{F}_n}^{-1}(p)}{T_{\mathbb{F}_n}^{-1}(1)}$ . These estimators are strongly uniformly consistent.

**Lemma 3.1:**

- $T_{\mathbb{F}_n}^{-1}(\bar{T}_{\mathbb{F}_n}^{-1})$  converges strongly and uniformly to  $T_F^{-1}(\bar{T}_F^{-1})$  in  $[0, 1]$ ;
- $T_{\mathbb{F}_n}(\bar{T}_{\mathbb{F}_n})$  converges strongly and uniformly to  $T_F(\bar{T}_F)$  in  $[0, T_F^{-1}(1)]$  ( $[0, 1]$ ).

**Proof:** The strong uniform convergence of  $T_{\mathbb{F}_n}^{-1}$  may be obtained as a special case of Theorem 2.1 of Barlow and Van Zwet (1969). Alternatively, taking into account that the functional  $F \rightarrow Z_F(x)$  is continuous in  $F$ , pointwise a.s. convergence of  $Z_{\mathbb{F}_n}(\mathbb{F}_n^{-1}(p))$ , for every  $p$ , follows by the continuous mapping theorem, combined with the fact that empirical quantiles converge strongly to true quantiles. Then, uniform a.s. consistency follows by the same arguments of the Glivenko–Cantelli theorem. Since  $T_{\mathbb{F}_n}^{-1}$  is bounded and has bounded domain, its inverse function  $T_{\mathbb{F}_n}$  is also strongly uniformly consistent. Since  $T_{\mathbb{F}_n}^{-1}(1)$  converges a.s. to  $T_F^{-1}(1)$ , it is clear that the same results hold for  $\bar{T}_{\mathbb{F}_n}^{-1}$  and, likewise, for  $\bar{T}_{\mathbb{F}_n}$ . ■

Henceforth, we will abbreviate  $T_{\mathbb{F}_n}^{-1}$  and  $\bar{T}_{\mathbb{F}_n}^{-1}$  with  $T_n^{-1}$  and  $\bar{T}_n^{-1}$ , respectively, whenever it will be clear from the context that they correspond to a sample from  $\mathbb{F}_n$ .

Note that under the IOR constraint,  $T^{-1}$  is concave. Therefore, an IOR estimator may be constructed using  $(T_n^{-1})_{cv}$ , namely, the LCM of  $T_n^{-1}$ . In fact,  $(T_n^{-1})_{cv}$  is a concave piecewise linear function, so it always has a right derivative, denoted as  $\partial_+(T_n^{-1})_{cv}$ , which, by construction, is a decreasing right-continuous step function. Accordingly, the relation in (2) may be used to obtain an increasing estimator of the OR, defined as follows:

$$\tilde{\lambda}_n(x) = \frac{1}{\partial_+(T_n^{-1})_{cv} \circ \mathbb{F}_n(x)}, \text{ for } x \in (0, X_{(n)}),$$

whereas  $\tilde{\lambda}_n(x) = 0$ , for  $x \leq 0$ , and  $\tilde{\lambda}_n(x) = +\infty$ , for  $x \geq X_{(n)}$ . In other words,  $\tilde{\lambda}_n(x)$  is the reciprocal of the slope (from the right) of  $(T_n^{-1})_{cv}$ , evaluated at the point  $\mathbb{F}_n(x)$ . Accordingly, the odds function is estimated by

$$\tilde{\Lambda}_n(x) = \int_0^x \tilde{\lambda}_n(t) dt = \int_0^x \frac{1}{\partial_+(T_n^{-1})_{cv} \circ \mathbb{F}_n(t)} dt. \quad (3)$$

Finally, an IOR estimator of  $F$  is given by

$$\tilde{\mathbb{F}}_n = L \circ \tilde{\Lambda}_n = 1 - \frac{1}{1 + \tilde{\Lambda}_n}.$$

$\tilde{\mathbb{F}}_n$  is clearly IOR, and it is absolutely continuous, except in the right endpoint of its support,  $X_{(n)}$ , at which it has a jump. Correspondingly, the PDF  $f$  can be estimated, in  $(0, X_{(n)})$ , as

$$\tilde{f}_n = \frac{\tilde{\lambda}_n}{(1 + \tilde{\Lambda}_n)^2}. \quad (4)$$

Using the methods described in the book of Robertson et al. (1988), it is possible to establish the asymptotic properties of these estimators.

**Theorem 3.2:** *Assume that  $F$  is IOR, then:*

- (1)  $\tilde{\lambda}_n \rightarrow \lambda$  almost surely and uniformly in  $[0, x_0]$ , for every  $x_0$  such that  $\lambda(x_0) < \infty$ ;
- (2)  $\tilde{\mathbb{F}}_n \rightarrow F$  almost surely and uniformly in  $[0, \infty)$ ;
- (3)  $\tilde{f}_n \rightarrow f$  almost surely and uniformly in  $[0, x_0]$ , for every  $x_0$  such that  $\lambda(x_0) < \infty$ .

**Proof:** Following the approach as in Theorem 7.4.1 of Robertson et al. (1988), we prove that  $\lambda(x_0^-) \leq \liminf_{n \rightarrow \infty} \tilde{\lambda}_n(x_0) \leq \limsup_{n \rightarrow \infty} \tilde{\lambda}_n(x_0) \leq \lambda(x_0^+)$ . Indeed, since the LCM  $(T_n^{-1})_{cv}$  is concave by construction, then, for some small  $\epsilon > 0$ , we have that

$$\begin{aligned} & \frac{(T_n^{-1})_{cv}(\mathbb{F}_n(x_0) + \epsilon) - (T_n^{-1})_{cv}(\mathbb{F}_n(x_0))}{\epsilon} \\ & \leq \partial_+(T_n^{-1})_{cv} \circ \mathbb{F}_n(x_0) = \frac{1}{\tilde{\lambda}_n(x_0^+)} \\ & \leq \frac{1}{\tilde{\lambda}_n(x_0^-)} = \partial_-(T_n^{-1})_{cv} \circ \mathbb{F}_n(x_0) \leq \frac{(T_n^{-1})_{cv}(\mathbb{F}_n(x_0)) - (T_n^{-1})_{cv}(\mathbb{F}_n(x_0) - \epsilon)}{\epsilon}, \end{aligned}$$

for every  $x_0 > 0$  and  $\epsilon \in (0, \min(F_n(x_0), 1 - F_n(x_0)))$ .  $T_n^{-1}$  converges uniformly to  $T^{-1}$  on  $[0, 1]$ , consequently, the Marshall's inequality (Groeneboom and Jongbloed 2014, Exercise 3.1) gives

$$\sup_{p \in [0,1]} |(T_n^{-1})_{cv}(p) - T^{-1}(p)| \leq \sup_{p \in [0,1]} |T_n^{-1}(p) - T^{-1}(p)| \longrightarrow 0,$$

with probability 1. Then, letting  $n \rightarrow \infty$  in the above inequality, we obtain

$$\begin{aligned} \frac{T^{-1}(F(x_0) + \epsilon) - T^{-1}(F(x_0))}{\epsilon} &\leq \limsup_{n \rightarrow \infty} \frac{1}{\tilde{\lambda}_n(x_0)} \\ &\leq \liminf_{n \rightarrow \infty} \frac{1}{\tilde{\lambda}_n(x_0)} \leq \frac{T^{-1}(F(x_0)) - T^{-1}(F(x_0) - \epsilon)}{\epsilon}, \end{aligned}$$

which gives the claimed bound allowing  $\epsilon \rightarrow 0$ . In particular,  $\tilde{\lambda}_n$  is uniformly strongly consistent at the continuity points of  $\lambda$ . Now, if  $\lambda$  is increasing and continuous on some compact set  $[0, x]$ ,  $\tilde{\lambda}_n$  converges uniformly to  $\lambda$  on  $[0, x]$ . Setting  $x = x_0$ , we obtain part 1). Subsequently, the dominated convergence theorem (note that  $\tilde{\lambda}_n$  is bounded on  $[0, x]$ ) implies  $\lim_{n \rightarrow \infty} \int_0^y \tilde{\lambda}_n(t) dt = \lim_{n \rightarrow \infty} \tilde{\Lambda}_n(y) = \int_0^y \lambda(t) dt = \Lambda(y)$ , for every  $y \in [0, x]$ . Therefore, since the CDF  $L$  is uniformly continuous in  $[0, \infty)$ , it follows that

$$\tilde{\mathbb{F}}_n(x) = L \circ \tilde{\Lambda}_n(x) \longrightarrow L \circ \Lambda(x) = F(x)$$

almost surely, for every  $x$ . Finally, following the same arguments in the proof of the Glivenko–Cantelli theorem, we can ensure that  $\tilde{\mathbb{F}}_n \rightarrow F$  almost surely and uniformly in  $[0, \infty)$ . Since  $f(x) = \lambda(x)(1 - F(x))^2$  and, writing  $\tilde{\Lambda}_n = \Lambda_{\tilde{\mathbb{F}}_n}$ , we may express  $\tilde{f}_n(x) = \tilde{\lambda}_n(x)(1 - \tilde{\mathbb{F}}_n(x))^2$ . Then, part (1) and part (2) imply that  $\tilde{f}_n \rightarrow f$  strongly and uniformly in  $[0, x_0]$ . ■

### 3.1. Simulations

We illustrate the numerical performance of  $\tilde{\mathbb{F}}_n$  and  $\mathbb{F}_n$  in terms of MSE, as is well known,  $\text{MSE}(\mathbb{F}_n(x)) = \frac{1}{n}F(x)(1 - F(x))$ . With regard to  $\tilde{\mathbb{F}}_n$ , the MSE was simulated using the following distributions: (i) log-logistic,  $F(x) = \frac{1}{1+x^{-a}}$ ,  $a > 0$ , hereafter LL( $a$ ), which is IOR for  $a > 1$  and has a constant OR for  $a = 1$ ; (ii) Weibull  $F(x) = 1 - e^{-x^a}$ ,  $a > 0$ , hereafter W( $a$ ), which is IOR for  $a \geq 1$  (and also log-concave, IHR, IHRA and DMRL); (iii) beta type II,  $F(x) = \beta(\frac{x}{1+x}; a, b)$ ,  $a, b > 0$ , hereafter B2( $a, b$ ), which is IOR for  $a > 1, b \geq 1$  ( $\beta$  denotes the regularised incomplete beta function); (iv) the Haupt and Schabe's distribution (Haupt and Schabe 1997)  $F(x) = \sqrt{a^2 + (2a + 1)x} - a$ ,  $a > -1/2, x \in [0, 1]$ , hereafter HS( $a$ ), which is bathtub for  $a \in (\frac{1}{2}, 1)$  and IOR at the same time. Bear in mind that the majority of the shape conditions which are commonly used for order-restricted inference under an 'adverse ageing scenario' (log-concavity, IHR, IHRA, DMRL) require the existence of all moments, however, among the distributions considered, only the W and the HS distributions have all moments, whereas the LL( $a$ ) has an infinite moment of order  $a$ , and the B2( $b$ ) has an infinite moment of order  $r \geq b$ . Note also that scale parameters are conveniently not considered in our analysis, since ageing properties are scale invariant. Figure 1 illustrates the estimators  $\tilde{\mathbb{F}}_n$  and  $\mathbb{F}_n$  in the IOR case, for a small sample size.

**Figure 1.** Simulated small sample ( $n = 20$ ) from the IOR distribution HS(0.6). The plot on the left shows the CDFs  $F$  (dot-dashed),  $\mathbb{F}_n$  (solid) and  $\tilde{\mathbb{F}}_n$  (dashed); the plot on the right shows  $\lambda_F$  (dot-dashed) and  $\tilde{\lambda}_n$  (dashed).

Differently, the behaviour of such estimators in the non-IOR case is discussed in the next section and depicted in Figure 6.

In Figures 2 and 3, we plot simulated MSE values at all percentiles, based on 1000 runs, standardised by the corresponding ones for  $\mathbb{F}_n$ , that is,  $\frac{\text{MSE}(\tilde{\mathbb{F}}_n(x))}{\text{MSE}(\mathbb{F}_n(x))}$ . The simulation results show that when  $F$  is IOR,  $\tilde{\mathbb{F}}_n$  often outperforms  $\mathbb{F}_n$ , especially for small and large deciles. This is particularly visible for small sample sizes, as clearly when  $n$  grows both estimators converge to  $F$ . According to our results, the largest improvements often occur in the left tails, around deciles 0.1–0.3; however, in some cases  $\tilde{\mathbb{F}}_n$  performs worse at very small percentiles (0.01–0.05) for very small sample sizes ( $n = 10$ ) and some particular models. In terms of MSE, the variance of  $\tilde{\mathbb{F}}_n$  plays a critical role compared with the bias, for example, for the smallest sample size  $n = 10$  the variance is generally more than 90% of the corresponding MSE, while for larger sample sizes, such as  $n = 100$ , the bias is almost null. It can also be noted that convergence is somewhat slower for distributions with infinite variance. The case of the LL(1) is especially critical, because, besides having an infinite mean, it has a constant OR, so we expect no improvement, or less, compared to the cases in which the OR is strictly increasing. Surprisingly, even in this case,  $\tilde{\mathbb{F}}_n$  performs slightly better than  $\mathbb{F}_n$  for smaller sample sizes, whereas, for larger samples,  $\tilde{\mathbb{F}}_n$  performs better at the tails and  $\mathbb{F}_n$  performs better around the median.

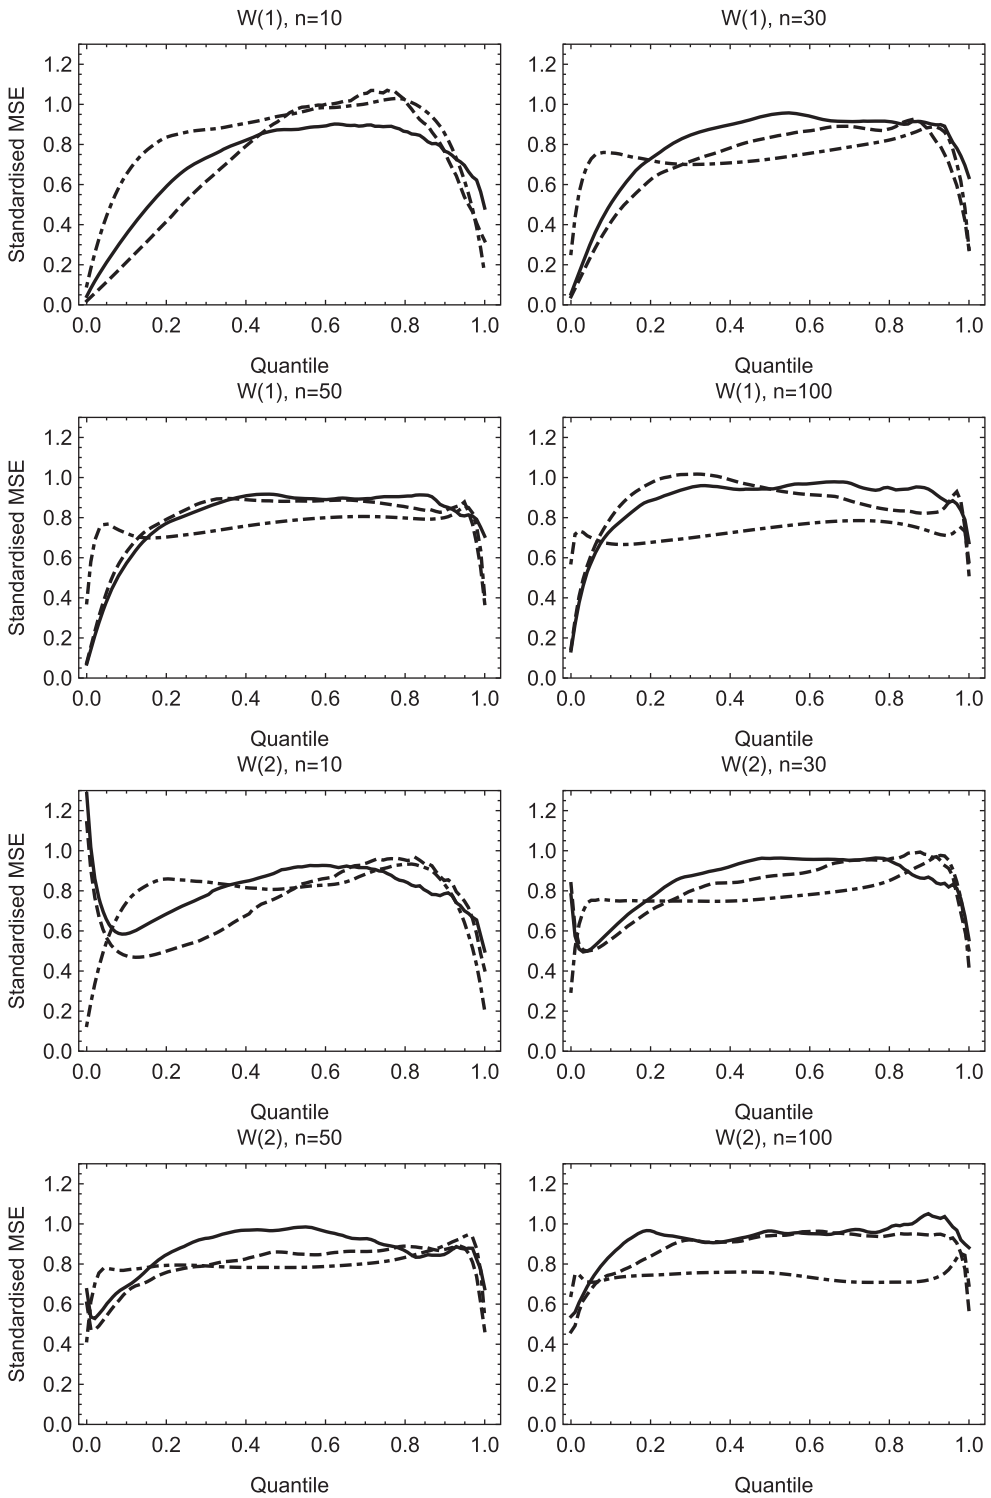

With regard to the Weibull family, note that only the  $W(a)$ , for  $a \geq 1$ , satisfies all the aforementioned shape properties, besides being IOR. In this case, it is interesting to compare  $\tilde{\mathbb{F}}_n$  with other shape-restricted estimators, obtained under log-concavity (see Dümbgen and Rufibach (2009, 2016) for details and computational aspects) and under IHR (Robertson et al. 1988, Ch. 7), and denoted as  $\tilde{\mathbb{F}}_n^{LC}$  and  $\tilde{\mathbb{F}}_n^{IHR}$ , respectively. We recall that log-concavity implies IHR, which in turn implies IOR. It is reasonable to expect that a stronger shape restriction leads to a stronger improvement. This is supported by the numerical results, represented in Figure 3. In particular,  $\tilde{\mathbb{F}}_n^{LC}$  seems to provide the best overall performance, and, in turn,  $\tilde{\mathbb{F}}_n^{IHR}$  slightly outperforms  $\mathbb{F}_n$ , although this may depend on the quantile, the sample size, and the underlying distribution. However, these alternative estimators have less applicability compared to  $\tilde{\mathbb{F}}_n$ , as they do not work for the distributions considered in Figure 2.

**Figure 2.** Standardised MSE for  $n = 10$  (solid),  $n = 30$  (dashed),  $n = 50$  (dot-dashed),  $n = 100$  (dotted), evaluated at all percentiles.

### 3.2. Smoothed estimators

One may wonder whether the improvement of  $\tilde{\mathbb{F}}_n$  over  $\mathbb{F}_n$  depends on the fact that  $\tilde{\mathbb{F}}_n$  is a smooth function. In response to this, a numerical comparison of  $\tilde{\mathbb{F}}_n$  with kernel estimators of the CDF, may show that the MSE of  $\tilde{\mathbb{F}}_n$  is often smaller even in this case, suggesting that the improvement of  $\tilde{\mathbb{F}}_n$  over  $\mathbb{F}_n$  depends mostly on shape aspects, rather than on smoothness. Although the objective of this paper is to estimate the CDF, we will now briefly discuss the possibility of obtaining smooth estimators even for the PDF. In fact, while  $\tilde{\mathbb{F}}_n$  is absolutely continuous in  $[0, X_{(n)})$ , the corresponding estimator of the PDF  $\tilde{f}_n$ , defined by (4), is typically discontinuous and may exhibit spikes at the observed points (see Figure 4). Hence, it is generally not a good pointwise estimator of  $f$ . For this reason, it may be interesting to

**Figure 3.** Standardised MSE for  $\tilde{\mathbb{F}}_n$  (solid),  $\tilde{\mathbb{F}}_n^{IHR}$  (dashed), and  $\tilde{\mathbb{F}}_n^{LC}$  (dot-dashed), evaluated at all percentiles.

**Figure 4.** Simulated small sample ( $n = 20$ ) from the IOR distribution  $B2(2,3)$ . The plot on the left shows the ORs  $\lambda_n^s$  (dot-dashed),  $\tilde{\lambda}_n$  (solid) and  $\lambda_{n,h}^s$  (dashed), for  $h = \frac{1}{4}$ ; the plot on the right shows  $f$  (dot-dashed),  $\tilde{f}_n$  (solid) and  $f_{n,h}^s$  (dashed).

obtain a smooth estimator of the PDF which preserves the OR properties of  $\tilde{f}_n$ , which may be achieved by smoothing the step function  $\tilde{\lambda}_n$  and then applying the approach discussed above.

Let  $k$  be a zero-mean PDF with support  $[-1, 1]$ , for technical convenience. Given a bandwidth  $h > 0$  define as usual  $k_h(x) = \frac{1}{h}k(\frac{x}{h})$ , and denote by  $K_h$  the corresponding CDF, that is,  $K_h(x) = \int_{-\infty}^x k_h(t) dt$ . A smooth version of  $\tilde{\lambda}_n$  is given by

$$\lambda_{n,h}^s(x) = \int k_h(x - t)\tilde{\lambda}_n(t) dt = \int (1 - K_h(x - t)) d\tilde{\lambda}_n(t),$$

after integration by parts. Therefore, as  $\tilde{\lambda}_n$  is increasing by construction, it follows immediately that  $\lambda_{n,h}^s$  is also increasing. Note that, since  $\tilde{\lambda}_n(x) = +\infty$ , for  $x \geq X_{(n)}$ , then  $\lambda_{n,h}^s(x) = +\infty$ , for  $x \geq X_{(n)} - h$ , hence the smoothing has an effect just at points smaller than  $X_{(n)} - h$ . Now, a convex estimator of  $\Lambda$  is given by  $\Lambda_{n,h}^s = \int_{-\infty}^x \lambda_{n,h}^s(t) dt$ , where, unlike (3), here the integration starts at  $-\infty$ , meaning that it assigns positive mass to the negative half line (this may be adjusted, if needed). Correspondingly, an IOR estimator of the CDF is defined as  $\mathbb{F}_{n,h}^s = L \circ \Lambda_{n,h}^s$ , and a smooth estimator of the PDF is given by  $f_{n,h}^s = \frac{\lambda_{n,h}^s}{(1 + \Lambda_{n,h}^s)^2}$ .

Since  $k$  has support  $[-1, 1]$ ,  $\lambda_{n,h}^s(x) = \int_{x-h}^{x+h} k_h(x - t)\tilde{\lambda}_n(t) dt$ . Therefore, by monotonicity,  $\tilde{\lambda}_n(t) \in [\tilde{\lambda}_n(x - h), \tilde{\lambda}_n(x + h)]$ , which holds for  $t \in [x - h, x + h]$ , implies that  $\lambda_{n,h}^s(x) \in [\tilde{\lambda}_n(x - h), \tilde{\lambda}_n(x + h)]$ . Then, if  $h \rightarrow 0$  as  $n \rightarrow \infty$ , the asymptotic behaviour of  $\lambda_n$ , proved in Theorem 3.2, entails that  $\lambda_{n,h}^s \rightarrow \lambda$  strongly and uniformly in  $[0, x_0]$  for every  $x_0$  such that  $\lambda(x_0) < \infty$ . So, using the same arguments as in the proof of Theorem 3.2,  $\mathbb{F}_n^s \rightarrow F$  uniformly in  $[0, \infty)$  and  $f_n^s \rightarrow f$  strongly and uniformly in  $[0, x_0]$ .

As usual in kernel estimation problems, the optimal choice of the bandwidth is the crucial issue. We are not dealing with this problem in the present paper, as the involved construction of  $\tilde{\lambda}_n$  makes it very hard to derive expressions for the MSE of  $\lambda_{n,h}^s$ . This estimator is also quite demanding from a computational point of view. As an illustration, Figure 4 shows  $\lambda_{n,h}^s$  and  $f_{n,h}^s$  for a sample of size  $n = 20$  from a  $B2(2,3)$  distribution, using the Epanechnikov kernel with bandwidth  $h = \frac{1}{4}$ , that is,  $k_{1/4}(x) = \frac{3}{4}(1 - 16x^2)$ ,  $x \in [-\frac{1}{4}, \frac{1}{4}]$ .

#### 4. Tests for the IOR property

Tests of different ageing properties, or, as discussed above, shape restrictions, have been discussed extensively in the literature: among many other authors, Proschan and Pyke (1967), Barlow and Proschan (1969), Bickel (1969) or Bickel and Doksum (1969) consider the null hypothesis of exponentiality versus the IHR alternative; Deshpande (1983), Kochar (1985), Link (1989), Wells and Tiwari (1991), and Ahmad (1994), consider the null hypothesis of exponentiality versus the IHRA alternative; while Tenga and Santner (1984), Hall and Van Keilegom (2005), Durot (2008), Groeneboom and Jongbloed (2012), Gijbels and Heckman (2004) or Lando (2022) consider the IHR null hypothesis versus the alternative that the HR is non-monotone. This approach, that is, setting the shape restriction as the null hypothesis, may be more demanding from a computational point of view, but it has several advantages in controlling the behaviour of the test. We follow this idea and study tests of the null hypothesis  $\mathcal{H}_0 : F \in \mathcal{F}_{IOR}$  versus  $\mathcal{H}_1 : F \notin \mathcal{F}_{IOR}$ . Following a conservative approach, this boils down to testing the null hypothesis that  $F$  has an LL(1) distribution, denoted as  $\mathcal{H}_0^L : F = L$ , versus  $\mathcal{H}_1$ , as the LL(1) represents the boundary between  $\mathcal{H}_0$  and  $\mathcal{H}_1$ . Tests of this kind have already been studied in Lando et al. (2022a), who focused on a restricted null hypothesis  $\mathcal{H}_0^v : \lambda \text{ is increasing in } S_v$ , where  $S_v = \{x : x \leq F^{-1}(1 - v)\}$ ,  $v \in (0, 1)$ . The domain restriction was necessary to control the behaviour of the test statistic, given by the maximum distance between the empirical odds function  $\Lambda_{\mathbb{F}_n} = \frac{\mathbb{F}_n}{1 - \mathbb{F}_n}$  and its GCM  $(\Lambda_{\mathbb{F}_n})_{cx}$ , due to the lack of uniform strong convergence of  $\Lambda_{\mathbb{F}_n}$  and  $(\Lambda_{\mathbb{F}_n})_{cx}$  to  $\Lambda_F$  under  $\mathcal{H}_0$ . Differently, transporting the testing problem to the maximum distance between the estimators  $\bar{T}_n$ , or  $\mathbb{F}_n$ , and their corresponding constrained versions  $(\bar{T}_n)_{cx}$ , or  $\widetilde{\mathbb{F}}_n$ , respectively, means that, under  $\mathcal{H}_0$ , we do have uniform strong convergence in the whole domain, hence restrictions are no longer necessary.

##### 4.1. A test based on the convexity of $\bar{T}$

Similarly to Tenga and Santner (1984), who deal with the IHR property, we may obtain a first test which detects departures from the IOR property by considering a suitable distance between  $\bar{T}_n$  and  $(\bar{T}_n)_{cx}$ , or, similarly,  $\bar{T}_n^{-1}$  and  $(\bar{T}_n^{-1})_{cv}$ . We will consider the following scale-independent test statistic

$$\text{KT}(\mathbb{F}_n) = \sup_{u \in [0,1]} |\bar{T}_n(u) - (\bar{T}_n)_{cx}(u)| = \max_{1 \leq i \leq n} \left| \frac{i}{n} - (\bar{T}_n)_{cx} \circ \bar{T}_n^{-1} \left( \frac{i}{n} \right) \right|.$$

It can be seen that, if the jump points of the empirical odds function  $\Lambda_{\mathbb{F}_n}$ , determined by the coordinates  $(X_{(i)}, \frac{i}{n-1})$ ,  $i = 1, \dots, n-1$ , lay on a convex curve, then  $\text{KT}(\mathbb{F}_n) = 0$ .

To obtain a conservative test, the determination of the least favourable distribution of KT under the null hypothesis is especially critical. As established in the following theorem, owing to a stochastic ordering result, such a distribution coincides with the distribution of KT in the case when the data are randomly sampled from the LL(1). To understand this behaviour, we need to introduce some additional notations. Let us denote  $\bar{Z}_F = \frac{Z_F}{T_F^{-1}(1)}$ , so that  $\bar{T}_F = F \circ \bar{Z}_F^{-1}$ , and define the functional

$$\Phi_p(F) = (F \circ \bar{Z}_F^{-1})_{cx} \circ \bar{T}_F^{-1}(p) = (\bar{T}_F)_{cx} \circ \bar{T}_F^{-1}(p).$$

The empirical counterpart of  $\Phi_p(F)$ , for  $p = \frac{i}{n}$ , is

$$\Phi_{i/n}(\mathbb{F}_n) = (\mathbb{F}_n \circ \overline{Z}_{\mathbb{F}_n}^{-1})_{cx} \circ \overline{T}_{\mathbb{F}_n}^{-1}\left(\frac{i}{n}\right) = (\overline{T}_{\mathbb{F}_n})_{cx} \circ \overline{T}_{\mathbb{F}_n}^{-1}\left(\frac{i}{n}\right).$$

Let us recall that  $X$  is larger than  $Y$  in the usual stochastic order, denoted as  $X \geq_{st} Y$ , if  $P(X \geq t) \geq P(Y \geq t)$ , for every  $t$  (Shaked and Shanthikumar 2007). We can now establish the following result.

**Theorem 4.1:** *Let  $\mathbb{L}_n$  be the empirical CDF corresponding to a random sample from  $L$ . Under  $\mathcal{H}_0$ ,  $\text{KT}(\mathbb{L}_n) \geq_{st} \text{KT}(\mathbb{F}_n)$ .*

**Proof:** Let  $L_n$  be a realisation of  $\mathbb{L}_n$ , corresponding to the observed sample  $(y_{(1)}, \dots, y_{(n)})$ . Since  $L \geq_c F$ , Theorem 1 of Lando et al. (2022b) implies that  $\Phi_{i/n}(\mathbb{F}_n) \geq_{st} \Phi_{i/n}(\mathbb{L}_n)$ , for  $i = 1, \dots, n$ , provided that

$$(\overline{T}_{F_n^*})_{cx} \circ \overline{T}_{F_n^*}^{-1}\left(\frac{i}{n}\right) = \Phi_{i/n}(F_n^*) \geq \Phi_{i/n}(L_n) = (\overline{T}_{L_n})_{cx} \circ \overline{T}_{L_n}^{-1}\left(\frac{i}{n}\right), \quad (5)$$

where  $F_n^* = F^{-1} \circ L \circ L_n = \tau \circ L_n$  is the empirical CDF corresponding to the values  $\tau(y_{(i)})$ , which determine an ordered sample from  $F$ . Let

$$u_i = \overline{T}_{L_n}^{-1}\left(\frac{i}{n}\right) = \frac{\sum_{j=1}^i \left(\frac{n-j+1}{n}\right)^2 (y_{(j)} - y_{(j-1)})}{\sum_{j=1}^n \left(\frac{n-j+1}{n}\right)^2 (y_{(j)} - y_{(j-1)})},$$

$$u_i^* = \overline{T}_{F_n^*}^{-1}\left(\frac{i}{n}\right) = \frac{\sum_{j=1}^i \left(\frac{n-j+1}{n}\right)^2 (\tau(y_{(j)}) - \tau(y_{(j-1)}))}{\sum_{j=1}^n \left(\frac{n-j+1}{n}\right)^2 (\tau(y_{(j)}) - \tau(y_{(j-1)}))}.$$

The denominators  $\theta = \sum_{j=1}^n \left(\frac{n-j+1}{n}\right)^2 (y_{(j)} - y_{(j-1)})$  and  $\eta = \sum_{j=1}^n \left(\frac{n-j+1}{n}\right)^2 (\tau(y_{(j)}) - \tau(y_{(j-1)}))$  are constant because the samples are fixed. We now define the function  $h : [0, 1] \rightarrow [0, 1]$  by

$$h(u_i) = h\left(\frac{1}{\theta} \sum_{j=1}^i \left(\frac{n-j+1}{n}\right)^2 (y_{(j)} - y_{(j-1)})\right)$$

$$= \frac{1}{\eta} \sum_{j=1}^i \left(\frac{n-j+1}{n}\right)^2 (\tau(y_{(j)}) - \tau(y_{(j-1)})) = u_i^*,$$

and by linear interpolation between the  $u_i$ 's values. The increments may be expressed as  $u_i - u_{i-1} = \frac{1}{\theta} \left(\frac{n-j+1}{n}\right)^2 (y_{(i)} - y_{(i-1)})$  and  $u_i^* - u_{i-1}^* = \frac{1}{\eta} \left(\frac{n-j+1}{n}\right)^2 (\tau(y_{(i)}) - \tau(y_{(i-1)}))$ , respectively. To prove (5), note that, under  $\mathcal{H}_0$ , the function  $\tau$  is increasing and concave, hence

$$\frac{h(u_{i+1}) - h(u_i)}{u_{i+1} - u_i} = \frac{\theta \tau(y_{i+1}) - \tau(y_i)}{\eta y_{i+1} - y_i} \leq \frac{\theta \tau(y_i) - \tau(y_{i-1})}{\eta y_i - y_{i-1}} = \frac{h(u_i) - h(u_{i-1})}{u_i - u_{i-1}}.$$

Therefore the slopes of the piecewise linear function  $h$  are decreasing, that is,  $h$  is concave. Now, Theorem 2.2 of Tenga and Santner (1984) yields (5). Subsequently, as  $\Phi_{i/n}(\mathbb{F}_n) \geq_{st}$

$\Phi_{i/n}(\mathbb{L}_n)$ ,  $\text{KT}(\mathbb{F}_n) = \max_i(\frac{i}{n} - \Phi_{i/n}(\mathbb{F}_n))$  and similarly  $\text{KT}(\mathbb{L}_n) = \max_i(\frac{i}{n} - \Phi_{i/n}(\mathbb{L}_n))$ , we obtain the desired result.  $\blacksquare$

Theorem 4.1 states that the random variable  $\text{KT}(\mathbb{L}_n)$  represents a stochastic (upper) bound for  $\text{KT}(\mathbb{F}_n)$  under the null hypothesis. Accordingly, the problem boils down to testing  $\mathcal{H}_0^L$ : ‘ $F$  is LL(1)’ against  $\mathcal{H}_1$ , so we reject  $\mathcal{H}_0$  when  $\text{KT}(F_n) \geq c_{\alpha,n}$ , where  $c_{\alpha,n}$  is the solution of  $P(\text{KT}(\mathbb{L}_n) \geq c_{\alpha,n}) = \alpha$ . Theorem 4.1 ensures that the probability of rejecting  $\mathcal{H}_0$  when it is true, is at most  $\alpha$ , that is, the test has size  $\alpha$  under  $\mathcal{H}_0$ . Similarly, if  $F$  is DOR, it is easy to see that  $P(\text{KT}(\mathbb{F}_n) \geq c_{\alpha,n}) \geq P(\text{KT}(\mathbb{L}_n) \geq c_{\alpha,n}) = \alpha$ , that is, the test is *unbiased* under DOR alternatives. For a given realisation  $F_n$ , the  $p$ -value of the test is  $p = P(\text{KT}(\mathbb{L}_n) \geq \text{KT}(F_n))$ .

As established by the following theorem,  $\text{KT}$  is also capable of detecting any deviation from the IOR null hypothesis.

**Theorem 4.2:** *Under  $\mathcal{H}_1$ ,  $\lim_{n \rightarrow \infty} P(\text{KT}(\mathbb{F}_n) > c_{\alpha,n}) = 1$ .*

**Proof:** If  $\mathcal{H}_0$  is true, considering the special case when  $\bar{T}_n$  is obtained by sampling from the LL(1),  $\bar{T}_n$  and  $(\bar{T}_n)_{cx}$  converge strongly and uniformly to the identity function. In particular, Marshall’s inequality gives  $\sup_{u \in [0,1]} |(\bar{T}_n)_{cx}(u) - u| \leq \sup_{u \in [0,1]} |\bar{T}_n(u) - u|$ , with probability 1. Then, for every fixed  $\alpha \in (0, 1)$ , there exists some  $n_0$  such that, for  $n > n_0$

$$P(\sup_u |\bar{T}_n(u) - u| \leq \frac{\epsilon}{2} \wedge \sup_u |(\bar{T}_n)_{cx}(u) - u| \leq \frac{\epsilon}{2}) \geq 1 - \alpha$$

However, the function  $u - \frac{\epsilon}{2}$  is convex, therefore, for  $n > n_0$ ,  $u - \frac{\epsilon}{2} \leq (\bar{T}_n)_{cx}(u) \leq \bar{T}_n(u) \leq u + \frac{\epsilon}{2}, \forall u$ , and by inclusion we obtain

$$P(-\epsilon \leq \bar{T}_n(u) - (\bar{T}_n)_{cx}(u) \leq \epsilon, \forall u) = P(\sup_u (\bar{T}_n(u) - (\bar{T}_n)_{cx}(u)) \leq \epsilon) \geq 1 - \alpha.$$

Since  $\epsilon$  can be arbitrarily small,  $c_{\alpha,n} \rightarrow 0$  for  $n \rightarrow \infty$ .

Suppose that  $\mathcal{H}_1$  is true. Then  $d = \sup_u (\bar{T}(u) - (\bar{T})_{cx}(u)) > 0$ . Moreover,  $\bar{T}_n$  converges strongly and uniformly to  $\bar{T}$ , whereas  $(\bar{T}_n)_{cx}$  converges strongly and uniformly to  $\bar{T}_{cx}$  (this can be seen using the same argument as in Theorem 3 of Lando (2022)). Therefore, given some  $\epsilon > 0$ , there exists some  $n_0$  such that, for  $n > n_0$ ,  $\sup_u |\bar{T}(u) - \bar{T}_n(u)| < \frac{\epsilon}{2}$  and  $\sup |(\bar{T}_n)_{cx}(u) - \bar{T}_{cx}(u)| < \frac{\epsilon}{2}$ , with probability 1. Then, for  $n > n_0$

$$\bar{T}_n(u) - (\bar{T}_n)_{cx}(u) > \bar{T}(u) - \frac{\epsilon}{2} - (\bar{T}_{cx}(u) + \frac{\epsilon}{2}) = \bar{T}(u) - \bar{T}_{cx}(u) - \epsilon$$

almost surely, for every  $u$ , which implies

$$\sup_u (\bar{T}_n(u) - (\bar{T}_n)_{cx}(u)) > \sup_u (\bar{T}(u) - \bar{T}_{cx}(u) - \epsilon) = d - \epsilon > 0.$$

Therefore, since  $\epsilon$  can be arbitrarily small,  $P(\sup_u (\bar{T}_n(u) - (\bar{T}_n)_{cx}(u)) \geq d) \rightarrow 1$ , for  $n \rightarrow \infty$ . But since  $c_{\alpha,n} \rightarrow 0$ , then  $P(\text{KT}(\mathbb{F}_n) > c_{\alpha,n}) \rightarrow 1$ .  $\blacksquare$

It is important to remark that one may replace the sup-norm with a different type of distance between  $(\bar{T}_n)_{cx}$  and  $\bar{T}_n$  and still obtain a consistent test, since the key steps in the proof of Theorem 4.2 are the uniform consistency of these two estimators under  $\mathcal{H}_0$ , while only  $\bar{T}_n$  converges to  $\bar{T}$  under  $\mathcal{H}_1$ .

### 4.2. A test based on $\widetilde{\mathbb{F}}_n$

A second test can be obtained by considering a suitable distance between  $\mathbb{F}_n$  and  $\widetilde{\mathbb{F}}_n$ , such as the uniform norm. Let us define the following Kolmogorov–Smirnov type test statistic

$$KS(\mathbb{F}_n) = \sup_{x>0} |\mathbb{F}_n(x) - \widetilde{\mathbb{F}}_n(x)|.$$

About the IHR property, a Kolmogorov–Smirnov test of this type has been studied by Lando (2022). Note that KS is also scale-independent. However, if the jump points of  $\Lambda_{\mathbb{F}_n}$  lay on a convex curve, then  $KS(\mathbb{F}_n)$  does not coincide with 0, differently from  $KT(\mathbb{F}_n)$ . To fulfil this property, one should consider a modified version of KS, say  $\widehat{KS}(\mathbb{F}_n) = \sup_{x>0} |\widehat{\mathbb{F}}_n(x) - \widetilde{\mathbb{F}}_n(x)|$ , where  $\widehat{\mathbb{F}}_n$  has the same construction of  $\widetilde{\mathbb{F}}_n$ , as described in Section 3, with the exception that it does not include any shape constraint, namely,

$$\widehat{\mathbb{F}}_n(x) = L \left( \int_0^x \frac{1}{\partial_+(T_n^{-1}) \circ \mathbb{F}_n(t)} dt \right).$$

$\widehat{\mathbb{F}}_n$  and  $\mathbb{F}_n$  are very similar and it is easy to see that they are asymptotically equivalent, moreover, the computation of  $\widehat{\mathbb{F}}_n$  is quite demanding without having an improvement on the power of the test. Therefore, henceforth we will focus only on KS.

As in the previous subsection, the distribution of KS may be determined by simulating from  $L$ . Since  $\widetilde{\mathbb{F}}_n$  is based on transformations starting from  $(T_n^{-1})_{cv}$ , the basic idea is that the empirical transform  $T_n^{-1}$  obtained from strictly IOR distributions will have fewer deviations from concavity, compared to the that obtained from a sample from the LL(1) (for which  $T^{-1}$  is linear). Accordingly, one may expect that KS tends to provide larger values in the LL(1) case, compared to the strict IOR case. However, differently from KT, the stochastic ordering arguments used in Theorem 4.1 do not hold for KS, because of the complicated construction of  $\widetilde{\mathbb{F}}_n$ . Accordingly, we cannot formally establish a stochastic bound for the size of the test under  $\mathcal{H}_0$ , so it is more correct to present this as a test for  $\mathcal{H}_0^L$  against  $\mathcal{H}_1$ . We reject the null  $\mathcal{H}_0^L$  when  $KS(F_n) \geq c_{\alpha,n}$ , where  $c_{\alpha,n}$  is the solution of  $P(KS(\mathbb{I}_n) \geq c_{\alpha,n}) = \alpha$ , while the  $p$ -value is  $p = P(KT(\mathbb{I}_n) \geq KT(F_n))$ . Simulating from  $L$  does not ensure a conservative behaviour, as in Theorem 4.1, although even in some critical IOR cases, numerical evidence shows that the type-I error of KS is always smaller than  $\alpha$  (as reported in the next subsection). Moreover, the test is consistent against non-IOR alternatives, as established by the following theorem. The proof is omitted because it can be obtained using the same arguments as in the proof of Theorem 3 of Lando (2022).

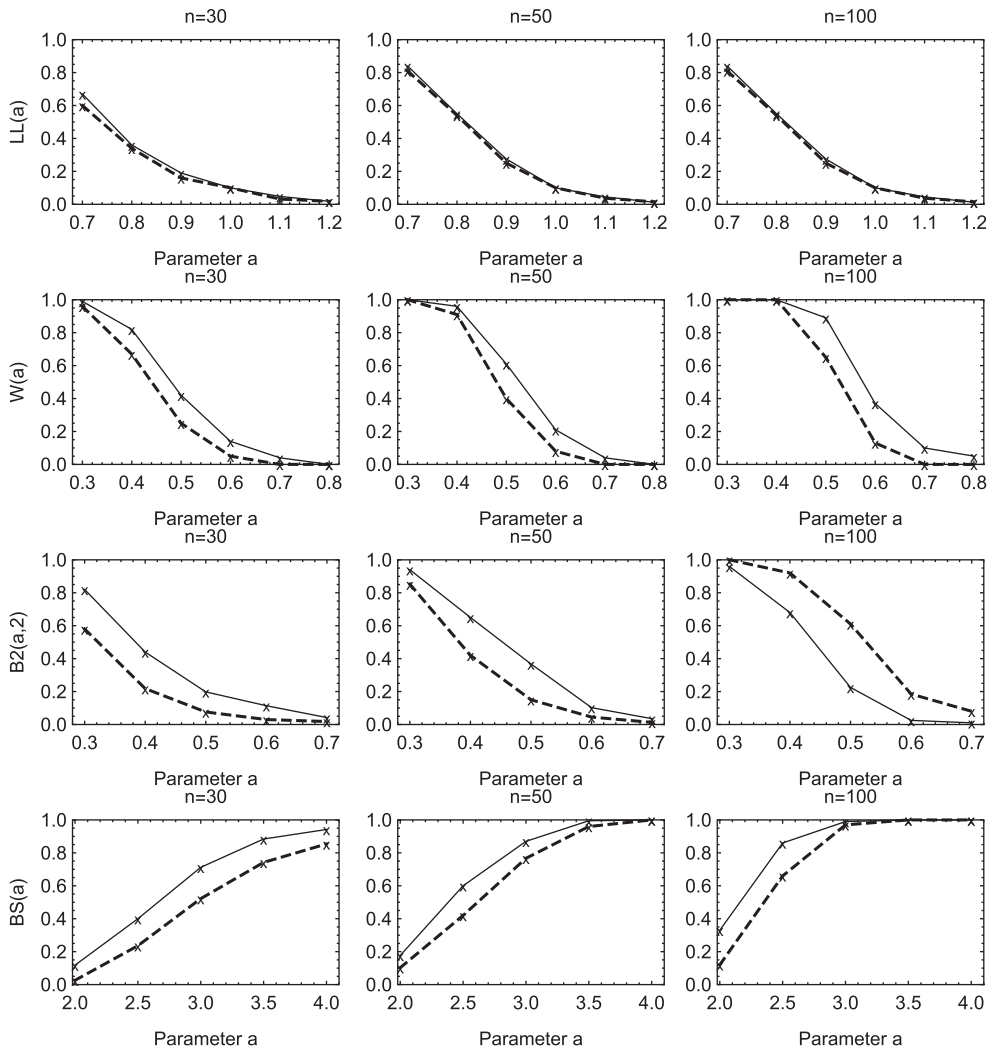

**Theorem 4.3:** *Under  $\mathcal{H}_1$ ,  $\lim_{n \rightarrow \infty} P(KS(\mathbb{F}_n) > c_{\alpha,n}) = 1$ .*

Similarly to what has been discussed in the previous subsection, one may replace the sup-norm with a different type of distance between  $\widetilde{\mathbb{F}}_n$  and  $\mathbb{F}_n$ , and the corresponding test would still be consistent.

### 4.3. Simulations

We compare the performance of the two tests proposed simulating from some popular parametric families of distributions. As these tests are scale invariant, we set the scale

**Figure 5.** Rejection rates (displayed on the x-axis) at the level  $\alpha = 0.1$  of KS (solid) and KT (dashed) under particular distributional assumptions. The first row shows that the type-I error of both tests is below  $\alpha$ , as the LL distribution is IOR for  $a \geq 1$  (the value of  $a$  is displayed on the y-axis).

parameters to 1. Some special cases of interest are (i) IOR models, (ii) decreasing OR (DOR) models, (iii) non-monotone OR models. As for (i), we consider the LL( $a$ ), with shape parameter  $a$  ranging in the interval  $[1, 1.2]$ . With regard to (ii), we consider the LL( $a$ ) with  $a \in [0.7, 1)$ . These cases are especially difficult to detect because, for  $a = 1$ , the OR is constant. As for (iii), we consider the W( $a$ ) with shape parameter  $a \in [0.3, 0.8]$ , which exhibits a decreasing–increasing OR for  $a < 1$ ; the B2 distribution, which has an increasing–decreasing OR for  $a < 1$  and  $b > 1$ , (thus we consider  $b = 2$ ,  $a \in [0.3, 0.7]$ ); and the Birnbaum–Saunders (BS) distribution with CDF  $\Phi(\frac{1}{a}(\sqrt{x} - \frac{1}{\sqrt{x}}))$ ,  $x, a > 0$  ( $\Phi$  denotes the standard normal CDF), which has an increasing–decreasing–increasing OR for  $a \in [2, 4]$  (this is especially critical to detect for smaller values of  $a$ ). The results are reported in

**Figure 6.** Simulated sample ( $n = 50$ ) from the non-IOR CDF  $F_{5,1} \cdot \bar{T}_n$  and  $(\bar{T}_n)$  on the left side;  $\mathbb{F}_n$  and  $\tilde{\mathbb{F}}_n$  on the right side. In both cases, the two estimators (constrained and unconstrained) diverge for quantile values larger than 0.2, approximately.

**Figure 7.** Plots of  $\mathbb{F}_n$  (step function) and  $\tilde{\mathbb{F}}_n$ .

Figure 5, which show the rejection rates at level  $\alpha = 0.1$ , corresponding to 500 simulation runs. The plots show that the performance of the tests is very similar when  $\mathcal{H}_0$  is true ( $LL(a)$  with  $a \geq 1$ ) and against DOR alternatives ( $LL(a)$  with  $a \leq 1$ ). In particular, it can be seen that, for both tests, in the IOR case the simulated type-I error probability is always bounded by  $\alpha$ , whereas, in the DOR case, the simulated power is always greater than  $\alpha$ . About KT, this is formally established by Theorem 4.1, which represents an advantage. However, it can be seen from Figure 5 that KS remarkably outperforms KT when  $F$  has a non-monotone OR, which is typically the most critical case to detect. For both tests, the simulated power increases with the sample size, confirming the consistency properties established in Theorem 4.2 and Theorem 4.3.

To illustrate the behaviour of KT and KS under non-IOR alternatives, we also consider the following CDF,

$$F_{a,b}(x) = \begin{cases} \frac{x^a}{x^a + 1} & 0 < x \leq 1, \\ \frac{x^b}{x^b + 1} & x > 1, \end{cases} \quad a, b > 0.$$

For  $a, b \geq 1$ , the OR of this distribution is increasing almost everywhere; however, for  $a > b$ , it has a downward jump at  $x = 1$ , so that  $F_{a,b}$  cannot be IOR. Figure 6 shows the remarkable distance between  $\bar{T}_n$  and  $(\bar{T}_n)$ , and between  $\mathbb{F}_n$  and  $\tilde{\mathbb{F}}_n$ , for a simulated sample of size 100 from  $F_{5,1}$ . In both cases, these large distances lead to the rejection of  $\mathcal{H}_0$ .

#### 4.4. An example

Nelson (2003, p. 105) provides a sample of 19 times to breakdown of an insulating fluid between electrodes at the voltage of 34 kV. By applying the test for the IHR property of Lando (2022), we obtain an approximate  $p$ -value of 0.02, which leads to the rejection of the IHR hypothesis. However, to test if the data conform to the ‘adverse ageing’ concept, we may apply a test for the weaker IOR property, in particular, we obtain  $\text{KT}(\mathbb{F}_n) = 0.21$  and  $\text{KS}(\mathbb{F}_n) = 0.14$ , and the corresponding approximate  $p$ -values are of 0.5 for KT and 0.42 for KS. These results provide some empirical evidence supporting the IOR null hypothesis, and accordingly one may estimate the underlying distribution using  $\tilde{\mathbb{F}}_n$ , which is depicted in Figure 7.
