## Acknowledgments

First I'd like to thank my supervisors Prof. Dr. Rui Ferreira Marques and Prof. Dr. Francisco Alves for their invaluable guidance, support and friendship throughout the last two years. I would also like to thank my colleague Hugo Moreira for his help and the insightful conversations about our work that in the end made this thesis go forward.

To my friends from the Physics Department, Pedro, Mortágua, Galhardo, Marcos, Fred, Mamede, Gafeira, Susana and Inês, thank you, for all the good times we spent in the last years, for all the entertaining conversations and mostly for the amazing friendships. My special thanks go to João, Tiago and Pedro Melo for being my partners in crime for most of the last years. Going through some courses without their companionship and help would've been a near to impossible task.
My deepest thanks go to my friends and colleagues at ICNAS, Cátia, Dalila, Joana, Sónia, Sara, João, Daniel, Ricardo and Vítor for supporting me both professionally as well as personally. The last few months have been nothing short of some of the best times I've ever had and I have all of you to thank for that. You will never be forgotten.

To Dora, words cannot express how grateful I am for all your support, patience and love. In some way, this work is as much mine as it is yours since I know that without you I wouldn't have gotten this far.
Finally, I'd like to thank my family and especially my parents for being my pillar of strength through good and bad times and for teaching me the most valuable lesson I've ever learned: never give up. You are both, and will always be, my utmost inspiration for everything that I am and wish to become in this life.

## Esboço do trabalho

O primeiro capítulo debruça-se sobre os objectivos deste trabalho bem como sobre os conceitos físicos elementares para a compreensão de todo o processo de produção de radionuclídeos num ciclotrão.

No segundo capítulo pretende-se fazer considerações teóricas sobre a viabilidade da produção de gálio-68 num ciclotrão, sendo que isto envolve estudar a escolha da reacção pretendida da qual se retirará o elemento alvo; a forma química do material alvo; as possíveis impurezas criadas durante o processo de irradiação; as quantidades de gálio-68 que em teoria se pode produzir em determinadas condições.

No terceiro capítulo, usando muita da informação feita no estudo teórico, realizouse uma experiência que consistiu na irradiação de uma solução de cloreto de zinco (natural), com o intuito de verificar que se pode produzir gálio-68. Através da medição da actividade da solução irradiada em função do tempo, verificou-se que é produzido gálio-68 bem como os outros radioisótopos previstos nos cálculos do segundo capítulo.
No quarto capítulo apresenta-se as conclusões do trabalho bem como as sugestões para trabalho futuro, sendo que é de destacar os fortes indícios para que esta técnica de produção de gálio-68 possa vir a tornar-se uma forma comum de produção em centros com ciclotrão.

## Outline

The first chapter focuses on the objectives of this work as well as the physical concepts required to understand the entire production process of radionuclides in a cyclotron.
The second chapter aims at making theoretical considerations on the viability of the production of gallium-68 in a cyclotron. This involves studying the choice of reaction from which the target material will be chosen; the chemical form of the target material; the possible impurities created during the irradiation process; the gallium-68 yields that can be obtained in theory under certain conditions.

In the third chapter, using much of the information obtained from the theoretical study, and experiment was performed in a cyclotron that consisted in the irradiation of a (natural) zinc chloride solution to show that it is possible to produce gallium-68 and in amounts that are consistent with the predicted yields from chapter 2.
In the fourth chapter the conclusions are presented as well as the suggestions for future work, leaving strong evidence that this production technique might become a standard of production in facilities with cyclotrons.

## 1. Introduction

### 1.1. Motivation and objectives

This work is essentially a theoretical and experimental physical study that aims at establishing the production viability of gallium-68 (half-life 68 min .) in a low energy cyclotron, for usage as a PET radioisotope in clinical practice as well as research studies.

The interest of radiopharmaceuticals that use gallium-68 as a tracer has been growing over the past few years due to a number of reasons.
Firstly, its simple complexation chemistry allows the production of tracers labeled with gallium-68 in an automated manner without the separation of excess precursor [Wes13].
Another highly relevant factor for the rising interest in gallium-68 has to do with one of the chelating agents used, the DOTA agent, that allows the production of diagnostic pharmaceuticals (the ones labeled with gallium-68, e.g.) but also pharmaceuticals for radionuclide therapy (labeled with lutetium-177). This is a highly advantageous in the sense that the diagnosed tumors are most certainly bound to be ones targeted in the radionuclide therapy $\left[\mathrm{BCG}^{+} 11\right]$.
The most common method to obtain gallium-68 is through a germanium-68 generator (half-life is 271 days), making it a source with an estimated lifespan of one year.
The ${ }^{68} \mathrm{Ge} /{ }^{68} \mathrm{Ga}$ generator works by using germanium- 68 which continuously decays by electron capture to gallium-68. Germanium is embedded in a sorbent material that is in turn eluted with an HCl solution in order to recover the gallium found to be in its ionic form $\mathrm{Ga}^{3+}$. The solution is then passed through a cation exchange column where the gallium is retained. A typical generator can be eluted every 4 h to obtain 35 mCi of gallium- 68 which in turn allows for 3 doses of 4 mCi in the early stages of the generators life. This causes a restriction for the amount of gallium-68 it is possible to use each day, which is especially problematic when trying to manage a facility that requires the isotope for both clinical and research procedures [SM13].
The reason for the widespread use of generators isn't only related to its straight forward use but also due to the fact that the vast majority of nuclear medicine facilities aren't equipped with a cyclotron and the ones that are usually restrict themselves to the production of the most common isotopes. The facilities that
resort to the production of gallium-68 in their cyclotron use a solid target assembly. This assembly usually works by using a thin electrodeposited layer of zinc-68 in a copper backing that is then irradiated by the cyclotron's beam. The irradiated disk is then dropped in a automated tray that transports the irradiated disk from the cyclotron room to a chemistry module outside of the cyclotron vault, where all the chemical procedures are then performed. It's clear that the entire production facility be planned with all these constraints in mind and therefore making it hard to implement this production technique in already functioning cyclotrons, leaving a gap for a production method that can avoid these problems.

The ability to produce gallium-68 on demand and without any of the restrictions imposed by the generator's dose limit would allow for an almost unlimited dose output, a better management of the clinical examinations and would provide researchers access to more gallium-68. Such a feat would undoubtedly boost the gallium-68 research in facilities that possess a cyclotron.

In order to bridge the already mentioned gap, this work will aim at developing a new route for the production of gallium-68, avoiding all the limitations of having a solid target assembly or a generator, by using a liquid solution as a target.

### 1.2. Theoretical Framework

### 1.2.1. Nuclear Reaction

Two particles (two nuclei or a nucleus and an elementary particle, e.g., a nucleon) enter into a strong nuclear interaction when they approach distances of about $10^{-13}$ cm . This results in a nuclear transformation and the process is called a nuclear reaction. These reactions involve momentum and energy redistributions of both particles which may lead to the creation of several other particles escaping from the region of interaction.

Depending on the particles responsible for these reaction, they can be classified as neutron-induced reactions, reactions induced by charged particles or by $\gamma$-quanta. Although the latter is associated with the electromagnetic interaction rather than the nuclear interaction, it is appropriate to label these reactions as nuclear reaction since the interaction takes place in the vicinity of the nucleus and results in its transformation.

The most common type of nuclear reaction involve a light particle $a$ and a nucleus $A$, resulting in the formation of a light particle $b$ and a nucleus $B$ :

$$
\begin{equation*}
a+A \rightarrow B+b \tag{1.1}
\end{equation*}
$$

or, in a shorthand notation,

$$
\begin{equation*}
A(a, b) B . \tag{1.2}
\end{equation*}
$$

If after the interaction, A and B are the same, except for their energy and momentum, then the interaction is called elastic scattering. If A and B are different then the interaction is called inelastic scattering.

A reaction may occur in serveral competing ways:

$$
a+A\left\{\begin{array}{l}
B+b \\
C+c \\
\cdots \\
A *+a \\
A+a
\end{array} .\right.
$$

The initial stage is called the entrance channel while the different possible ways in which a nuclear reaction may evolve in the second stage are called the exit channels of the reaction.

Momentum and energy aren't the only quantities conserved. Other quantities such as angular momentum, which influences the angular distribution of the products of a collision, parity, which leads to some selection rules which can sometimes forbid reactions that would otherwise be possible, are also conserved.

The investigation of a nuclear reaction aims at determining the reaction channels, the relative probability of its occurence through different channels for different energies of the incident particles, finding the energy and angular distribution of the reaction products.

### 1.2.1.1. Compound-nucleus reaction

The compound nucleus model was introduced by Bohr in 1936 and it assumes that $a$ enters the nucleus and suffers collisions with the nucleons of $A$, until it has lost all its incident energy and becomes a undistinguishable part of the nuclear constituents. This compound owes its name to the fact that both the incident particle $a$ and the target nucleus $A$ become lumped together in a state in which neither retain their identity. The compound nucleus is in an excited state due to the kinetic energy of $a$ and to the binding energy released when it is absorbed into the target nucleus. By definition, this system must be unstable since it can desintegrate into $a+A$, or into other final states [Boh36].
The compound nucleus may execute many cycles of its natural period before it disintegrates or emits a photon. What this means, in short, is that the energy transmitted by $a$ and distributed over all the nucleons is insufficient for any of them
to overcome the nucleus' potential. But due to the number of particles and the size of the system, the energy fluctuation is very high and some nucleons may gather enough energy to escape. This kind of reaction has a typical lifetime in the order of magnitude of $10^{-16} \mathrm{~S}$ [Alv02, Kra88].

### 1.2.1.2. Direct reaction

While the compound state is characterized by its long life in comparision with the expected transit time of incident particle across the nucleus, the reactions that occur in a time comparable to that transit time are called direct reactions. One of the most important properties of these reaction is that the energetic products of these reactions are not distributed isotropically in angle but concentrated at angles near the incident direction, which reflects that the incident particle makes one, or few, collisions with nucleons in the target nucleus and that its forward momentum is not transfered to an entire compound state

This kind of reaction occurs when there is considerable overlapping of the initial and final wave functions of the system leading to a very small transition time $\left(10^{-22} \mathrm{~s}\right)$. The probability of this mechanism can be understood in terms of the energy of incident particle and the resulting de Broglie wavelength - as the energy increases the wavelength $\lambda$ will become comparable to the size of the nucleons and therefore be more likely to interact with them [Kra88].

### 1.2.2. Cross-Section

In classical mechanics the probability of interaction between a point like projectile and a hard sphere is a deterministic phenomenon that depends only on the impact parameter and the area occupied by a section through the middle of the sphere, hence the name cross section. In nuclear physics, though the classical picture doens't apply, every nucleus inside a target occupies an effective area of interaction, $\sigma$. When an incoming particle strikes the target a reaction will occur if the projectile hits this effective area. In a target with thickness $d$, area $A$, and $N$ nuclei per unit volume, the effective area for a reaction to occur is $N(d A) \sigma$ and the reaction probability will therefore be the effective area divided by the total area $N(d A) \sigma / A$ (Fig. 1.1). Taking into account that this probability must be equal to the ratio of incoming particles and outgoing (reaction) particles $n_{r} / n_{i}$, then, [YH10]

$$
\begin{equation*}
n_{r}=n_{i} N d \sigma . \tag{1.3}
\end{equation*}
$$

The cross-section has dimension of an area and its unit is the barn (b), where[YH10, Alv02]

$$
1 \mathrm{~b}=10^{-28} \mathrm{~m}^{2} .
$$

Figure 1.1.: Incoming particles, target and outgoing particles scheme.

The value of a cross section for a particular reaction depends on the energy of the incident particles due to the energy width of the reaction. Because of this, it is more suitable to express the cross section values of a particular reaction in terms of the energy of the incoming particles. The resulting function is called an excitation function(Fig. 1.2).

Figure 1.2.: Example of an excitation function for the ${ }^{75} \mathrm{As}(p, n)^{75} \mathrm{Se}$ reaction [MQS88] .

In cyclotron physics, excitation functions play an especially important role when it comes to the choice of the energy range desired to favour a particular reaction when there are competing reactions.

Figure 1.3.: Competing reactions and the corresponding excitation functions. Because of the overlap of the competing reactions, it is necessary to tune the energy range in order to favor a particular reaction, in this case, to favor the ( $\mathrm{p}, \mathrm{n}$ ) reaction, the preffered energy range is $2-24 \mathrm{MeV}$ [MQS88].

### 1.2.3. Energy loss of heavy charged particles

The passage of particles through matter is characterized by two features:

1. Inelastic collisions with the atomic electrons of the material;
2. elastic scattering of the nuclei.

Of the two electromagnetic processes, inelastic collisions are almost sollely responsible for the loss of energy of particles in matter. These collisions have very high cross sections ( $\sigma \sim 10^{-17} \mathrm{~cm}^{2}$ ) and the energy is transfered to the atom and causes an ionization or excitation. The energy transfered is usually a very small fraction of the particles kinetic energy, but since the number of collisions per unit of path length is usually so high in dense matter, a very high energy loss is observed in even small layers. A 18 MeV proton loses all its energy in 3.45 mm of liquid water, for example. [ZZB10]
Elastic scattering from nuclei also occurs but not as frequently as electron collisions and in general there is very little transfered energy due to the fact that most materials' nuclei usually have much larger charge number than the incident particles, which in turn means that the impact parameter, that depends on the charge of the incoming particle and the target, will be high. The inelastic collisions are statistical in nature and occur with a certain quantum mechanical probability, but since their
number per path length is so high, one can, to a good approximation, work with the average energy loss per unit path length. This quantity is called the stopping power or $d E / d x$. [Leo94]
The energy loss of particles in matter can be described by Bethe's equation when studying non-relativistic particles [Bet30]:

$$
\begin{equation*}
-\frac{d E}{d x}=\frac{4 \pi z^{2} q_{e}^{4}}{m_{e} v^{2}} N Z \ln \left(\frac{2 m_{e} v^{2}}{I_{0}}\right) \tag{1.4}
\end{equation*}
$$

where, $m_{e}$ and $q_{e}$ are the mass and charge of the electron respectively, $z$ and v are the atomic number and velocity of the beam's particles and $Z$ and $N$ are the atomic number and number of atoms per volume unit of the target material crossed by the beam. $I_{0}$ corresponds to the value of the mean excitation potential of the atoms in the target material. It represents an average energy over all the bound electrons that can be transferred in an excitation process, including ionization. Its calculation is complex and experimental values can be found in the literature for most elements, but some semi-empirical expressions allow a good approximation:

$$
\begin{equation*}
\frac{I_{0}}{Z}=9.1\left(1+1.9 Z^{-\frac{2}{3}}\right) \mathrm{eV} \tag{1.5}
\end{equation*}
$$

For particles with relativistic velocities, Bethe's equation must be corrected [Alv02]:

$$
\begin{equation*}
-\frac{d E}{d x}=\frac{4 \pi z^{2} q_{e}^{4}}{m_{e} v^{2}} N Z\left(\ln \left(\frac{2 m_{e} v^{2}}{I_{0}}\right)-\ln \left(1-\beta^{2}\right)-\beta^{2}\right), \tag{1.6}
\end{equation*}
$$

where $\beta$ represents the ratio between the projectile's velocity and the speed of light. This formula is known as the Bethe-Bloch equation.
When studying compound targets' stopping power, it's a good first approximation to assume that the total stopping power will be the sum of the diffent elements' stopping power. This is true to some extent and translates Bragg's Rule but some corrections must be made when these calculations involve some light elements. The reason for this lies in the variation of the ionization potential, $I$, when the compound forms itself. The valence electrons' wave functions alter themselves and therefore so does the ionization potential which will tend to increase, leading to a greater average potential for all the electrons. This effect is less obvious in heavy elements because the number of electrons that participate in the chemical bond is smaller [BK05].

### 1.2.3.1. SRIM

In a work that involves calculating the energy loss of particles in matter and especially in compounds, it comes as a great advantage and inevitable step to use a
very established Monte Carlo simulation computer program, and that's where SRIM (Stopping and Range of Ions in Matter) comes into play. SRIM is a software package which calculate the stopping and range of ions into matter using a quantum mechanical treatment of collisions. Using statistical algorithms makes the calculation efficient because it allows the ion to make jumps between calculated collisions and then the program will average the collision results over the corresponding gap. One of SRIM's features that is especially prominent in this work is the way it calculates the stopping power of compounds. It uses a calculation method called the Core and Bond approach which suggests that the stopping power in compounds may be calculated using the superposition of stopping by atomic "cores", which would follow Bragg's rule, and then adding the contribution of the bonding electrons as a correction factor. SRIM uses this correction for compounds containing H, C, O, $\mathrm{N}, \mathrm{F}, \mathrm{S}$ and Cl because these small atoms have the largest bonding effect on stopping powers (Fig. 1.4).These corrections are not necessary for heavy atoms because experiments have shown that the deviation from Bragg's rule dissapears[Thw85] .

Figure 1.4.: Difference in stopping power between Bragg's rule and the Core and Bond model [ZZB10].

The most important program whithin SRIM is called TRIM (Transport of Ions in Matter) and it accepts complex targets made from compound materials. It can calculate 3D distribuition of the ions and the kinetic phenomenons associated with the ion's energy loss. It is especially useful to determine the average energy loss
from a large number of events and also to determine the average range of ions in a target. The output is then used not only to understand what energy the particles have when they actually strike the target, but also to calculate resulting yield from the reactions that occur [ZZB10].

### 1.2.4. Thick Target Yield

The amount of radionuclide that is expected to be produced by a particular nuclear reaction is obtained by the integration of the excitation function over a beam's energy range in a target. The absolute value of the produced radionuclides is of little practical interest without knowing the irradiation time for decay correction and so this has lead to a measuring standard called the thick target yield where "thick target" refers to the situation where the target's stopping power variation can no longer be considered infinitesimal. It is common for the thick target yield to be measured in a saturation condition. The saturation condition is fulfilled when the rate of decay equals the rate of production (assuming the rate of production is constant). This becomes clear when considering the following equations of decay [Alv02]:

$$
\begin{equation*}
\frac{d N(t)}{d t}=-\lambda N(t)+P \tag{1.7}
\end{equation*}
$$

where $\mathrm{N}(\mathrm{t})$ is the amount of radionuclides at a given time, $\lambda$ is the decay constant of the radioisotope and $P$ is the constant production rate. The solution for this equation is

$$
\begin{equation*}
A(t)=\lambda N(t)=P\left(1-e^{-\lambda t}\right) \tag{1.8}
\end{equation*}
$$

When $t$ becomes sufficiently large, the exponential will tend to zero and therefore the activity and the production rate will tend to equal themselves.
The thick target yield can be calculated from the following expression:[D.J08][Alv02]

$$
\begin{equation*}
Y=\frac{N_{A} H}{M z q_{e}} \int_{E_{\text {in }}}^{E_{\text {out }}}\left(\frac{d E}{d x}\right)^{-1} \sigma(E) d E \tag{1.9}
\end{equation*}
$$

where $N_{A}$ is Avogadro's number, $z$ is the projectile's atomic number and $q_{e}$ is the electron's charge. The integral is carried out over the beam's energy range, from the incoming energy $E_{\text {in }}$ to the outgoing energy $E_{\text {out }}$, and the integrand is the inverse of the medium's stopping power multiplied by the cross-section for the corrresponding value of the energy.
The typical units for the thick target yield in radioisotopes production practice is the $M B q / \mu A$ sat where sat indicates that this measure refers to a saturation condition.

The results of a thick target yield mesurement must be coherent with the theoretically predicted values albeit they still represent a measurement under specific target conditions, and therefore may vary.

### 1.2.5. ICNAS Cyclotron

The cyclotron at ICNAS is an IBA Cyclone 18/9 (Fig. 1.5)that is capable of bombarding targets with proton or deuteron beams ( 18 MeV for protons and 9 MeV for deuterons). The maximum beam currents announced by IBA are $150 \mu A$ for proton beams and $40 \mu A$ for deuterons. The beams are extracted by means of carbon foils (usually called strippers) which retain the ions' electrons thus inverting their trajectory and then collide with the target material.

Figure 1.5.: IBA Cyclone 18/9 (picture courtesy of ©IBA).
The target is one of the main components of a cyclotron and one of the most important elements of this work. A specific target exists for each radionuclide that is produced in a cyclotron. The reason for this lies in the different characteristics of the target materials such as density, thermal conductivity, physical form, chemical properties, etc... which require that a target be planned in different ways. The choice of the physical form of the target material is usually tied with the way the preparation of the end-product (radiopharmaceutical) is done. An example of this is the production of fluorine-18 that can be done in two distinctive ways: for the production of fluorodeoxyglusose, ${ }^{18} \mathrm{~F}$ - FDG, which uses the fluoride ion, the prefered way involves the irradiation of a liquid solution with ${ }^{18} \mathrm{O}$ because the synthesis of the of the radiopharmaceutical is done by reacting liquids. But it might be of interest to produce a radiophamaceutical that uses fluorine in a gaseous form due to some methods that involve the bubbling of fluorine gas, $\mathrm{F}_{2}$, through solutions of appropriate chemicals. In this case irradiation process is favoured by the ${ }^{20} \mathrm{Ne}(\mathrm{d}, \alpha)^{18} \mathrm{~F}$ where ${ }^{18} \mathrm{~F}_{2}$ is more easily isolated.

The liquid target, which ultimately will be the target of interest in this work, consists of a target chamber where the target material is inserted, a cooling mechanism, an insertion and extraction mechanism and a window to separate it from the inside of the cyclotron.

The material that the target chamber is made up of must be chosen while taking into account the following factors like the pH of the target material, its thermal conductivity which is of critical importance for the cooling of the target material, its resistance to radiation damage.
The cooling mechanism usually consists of a constant flow of cool water ( $\sim 2 \mathrm{~L} / \mathrm{min}$.) and is injected at the rear of the target (Fig. 1.6).

Figure 1.6.: Representation of a fluorine target with a water cooling mechanism. The arrows represent the path followed by the water around the target chamber where the beam's energy is deposited (picture courtesy of OIBA).

## 2. Targetry and Yields

### 2.1. Methodology

To study the viability of producing gallium-68 in a liquid target, the work must be divided into two distinct parts:

- First, the research of all the available reactions that yield the desired product and the consequent choice of the target element, the choice of the solution that is to be irradiated along with its characteristics, the determination of the impurities that are created and the determination of the ways in which their production can be minimised. With all this information in hand, and also by determining the materials that constitute the cyclotron target that will be used to perform the experiment, comes the computer simulation of the irradiation in order to determine the necessary physical quantities, such as the energy loss of protons in the target solution, in order to calculate the expected yield of radioisotope;
- Secondly, the experiment, with all the implementation challenges that arise from the fact that the cyclotron is routinely used for the production of ${ }^{18} \mathrm{~F}$ and ${ }^{11} \mathrm{C}$ for clinical use, which in practical terms means that before any irradiation is performed on an experimental target, every parameter must be double and triple checked to insure that no critical incident occurs that damages the cyclotron. Another critical aspect that is obvious because of the nature of the experiment, lies in the precaution needed because of the manipulation of substances with high activities or even because of the need to enter the cyclotron vault. Even after the experiment is performed, the data collection is a lengthy process ( $\sim 48 \mathrm{~h}$ ) which means that it must be carefuly articulated with the other tasks being performed at the facility. Other challenges include the fact that a cyclotron like the one at ICNAS, which is very oriented for the production of isotopes used in daily routine clinical practice, has very established working mechanisms such as the injection of target material $\left({ }^{18} \mathrm{O}\right.$ enriched water in the case of ${ }^{18} \mathrm{~F}$ and $N_{2}$ in the case of ${ }^{11} \mathrm{C}$ ) as well as their extraction, but when it comes to experiments, these processes become complicated mainly by the fact that they must be done manually and are subject to unexpected problems.

### 2.2. Choice of reaction

One of the first decisions encountered when doing a radioisotope production study is the choice of the reaction that will be used to produce the desired radioisotope. This decision depends on three main important factors,

1. the excitation function of reaction,
2. the available projectile types
3. the maximum beam energy of the projectiles.

In the case of the cyclotron at ICNAS the available projectiles are 18 MeV protons and 9 MeV deuterons, so we must look for reactions $A\left(\mathrm{p},{ }^{*}\right) \mathrm{Ga}-68$ or $B\left(\mathrm{~d},{ }^{*}\right) \mathrm{Ga}-68$.
The reactions that are available and that correspond to these requirements are presented in Fig. 2.1.

Figure 2.1.: Possible reactions' excitation functions[G.A77, GHAC63, $\mathrm{SBT}^{+} 98$, $\mathrm{OKO}^{+68]}$.

It is clear from the graph that the most suitable reaction is the ${ }^{68} \mathrm{Zn}(\mathrm{p}, \mathrm{n}){ }^{68} \mathrm{Ga}$ due to its higher cross section values. Moreover the maximum value of the excitation function is well within the energy range of the cyclotron's beam allowing for a very good thick target yield.

### 2.3. Choice of target medium

The target medium is one of the most critical points in the production of a radioisotope. The reaction choice provides the target element but the chemical form remains undetermined. There are several factors that must be taken into account when choosing the chemical form of the target medium:

- Regarding the chemical form, it should be chosen by taking into account the isotopic composition of its elements. While it is possible that when chosing a particular element, that none of its isotopes will have an entrance channel for a reaction that may create radioactive impurities, it is certainly true that by not taking this factor into account, the risk of doing so is increased. This is particularly clear in the case of the production of fluorine-18 where the most commonly used reaction is ${ }^{18} \mathrm{O}(\mathrm{p}, \mathrm{n})^{18} \mathrm{~F}$ and the preferred target is therefore enriched water $\left(\mathrm{H}_{2}{ }^{18} \mathrm{O}\right)$ instead of natural water. This is due to the fact that the isotopic abundance of ${ }^{18} \mathrm{O}$ in natural water is $0.2 \%$ whereas ${ }^{16} \mathrm{O}$ is $99.76 \%$ which would create a lot of ${ }^{13} \mathrm{~N}$ (half-life 9.96 min$)$ through the ${ }^{16} \mathrm{O}(\mathrm{p}, \alpha){ }^{13} \mathrm{~N}$ reaction and very little amount of ${ }^{18} \mathrm{~F}$;
- The physical state of the target medium should be liquid because this work aims at determining its viability in a cyclotron target .

In Tab. 2.1 is a list of the most common zinc compounds used in laboratories[P92].
Table 2.1.: List of zinc compounds along with their solubility and phase.

| Compound | Molar <br> Mass / <br> g.mol | Phase (25 <br> $\left.{ }^{\circ} \mathrm{C}\right)$ | Solubility <br> in water <br> $\left(25^{\circ} \mathrm{C}\right) /$ <br> g. $\mathrm{L}^{-1}$ | Solubility <br> in alcohol <br> $\left(25^{\circ} \mathrm{C}\right) /$ <br> g. $\mathrm{L}^{-1}$ |
| :---: | :---: | :---: | :---: | :---: |
| $\mathrm{ZnBr}_{2}$ | 225.198 | Solid | 4470 | Highly <br> soluble |
| $\mathrm{ZnCl}_{2}$ | 136.315 | Solid | 4320 | - |
| $\mathrm{ZnCrO}_{4}$ | 181.403 | Solid | Insoluble | - |
| $\mathrm{Zn(CN)}_{2}$ | 117.444 | Solid | 0.0005 | - |
| ZnI | 319.220 | Solid | 4500 | - |
| ZnO | 81.408 | Solid | Insoluble | - |

When deciding what compound to use some factors are of great importance:

- Solubility should be as high as possible because it is an indicator of how many target nuclei it is possible to have in the solution;
- The target solution should have as low vapor pressure as possible, as well as a high boiling temperature, because one of the critical parametres of a cyclotron target during irradiation is the pressure that builds up inside the target chamber. This is understandable if one takes into account that when the irradiation is occuring the target is sealed off from the exterior and therefore the energy deposited by the beam will make the pressure increase inside the chamber. Since highly volatile solutions have high vapor pressure, they are not suitable for cyclotron targetry;
- The compound must also be carefuly selected with respect to the by-products it might result in when irradiated. The most optimistic scenario would be one
where there are no nuclear reactions available in the chosen energy range but this is highly unlikely. The second best scenario is one where the by-product is stable and chemically inert.

The compound that respects these conditions is $\mathrm{ZnCl}_{2}$ since it is highly soluble in water. An aqueous solution is more suitable because its boiling point is higher than that of an alchool. The by product of the irradiation of Cl is ${ }^{37} \mathrm{Ar}$ (Tab. 2.3) which is gaseous at room temperature, inert and therefore forms no compounds, thus being easily separable from the rest of the solution[P92].

### 2.4. Isotopic and non-isotopic impurities

When irradiating a $\mathrm{ZnCl}_{2}$ solution it's inevitable for some impurities to be formed. There are two type of impurities:

- Isotopic impurities - different isotopes of the same target element will also produce isotopes of the desired product.
- Non-isotopic impurities are all the radioisotopes created that aren't isotopes of the desired product.

One of the ways to avoid producing isotopic impurities is to use isotopically enriched elements to make the target solution. Regarding this work specifically this would mean using zinc-68 instead of natural zinc. To demonstrate this reasoning Tab. 2.2 shows the isotopic composition of natural zinc, followed by the available reactions in the energy range and products.

Table 2.2.: Table showing the isotopic composition of zinc and available reactions in the $0-18 \mathrm{MeV}$ range[BW11].

| Isotope | Percentage of composition | $\left(\mathrm{p},{ }^{*}\right)$ reactions in $0-18$ <br> MeV range |
| :---: | :---: | :---: |
| ${ }^{64} \mathrm{Zn}$ | 49.17 | $(\mathrm{p}, \alpha)^{61} \mathrm{Cu} ;(\mathrm{p}, \gamma)^{65} \mathrm{Ga} ;$ <br> $(\mathrm{p}, \mathrm{n})^{65} \mathrm{Ga} ;(\mathrm{p}, \mathrm{n}+\mathrm{p})^{63} \mathrm{Zn}$ |
| ${ }^{66} \mathrm{Zn}$ | 27.73 | $(\mathrm{p}, 2 \mathrm{n})^{65} \mathrm{Ga} ;(\mathrm{p}, \gamma)^{67} \mathrm{Ga} ;$ <br> $(\mathrm{p}, \mathrm{n})^{66} \mathrm{Ga} ;(\mathrm{p}, \mathrm{x})^{65} \mathrm{Zn}$ |
| ${ }^{67} \mathrm{Zn}$ | 4.04 | $(\mathrm{p}, 2 \mathrm{n})^{66} \mathrm{Ga} ;(\mathrm{p}, \alpha)^{64} \mathrm{Cu} ;$ <br> $(\mathrm{p}, \gamma)^{68} \mathrm{Ga} ;(\mathrm{p}, \mathrm{n})^{67} \mathrm{Ga}$ |
| ${ }^{68} \mathrm{Zn}$ | 18.44 | $(\mathrm{p}, 2 \mathrm{n})^{67} \mathrm{Ga} ;(\mathrm{p}, \alpha)^{65} \mathrm{Cu} ;$ <br> $(\mathrm{p}, \mathrm{n})^{68} \mathrm{Ga} ;$ |
| ${ }^{70} \mathrm{Zn}$ | 0.61 | $(\mathrm{p}, \alpha)^{67} \mathrm{Cu} ;(\mathrm{p}, \mathrm{n})^{70} \mathrm{Ga} ;$ <br> $(\mathrm{p}, \mathrm{n}+\mathrm{p})^{69 \mathrm{man}} \mathbf{Z n} ;(\mathrm{p}, \mathrm{x})^{67} \mathrm{Cu} ;$ <br> $(\mathrm{p}, \mathrm{x})^{65} \mathrm{Zn}$ |

Aside from the isotopic impurities created, some non-isotopic are also created due to irradiation of the other elements present in the target medium. These impurities are summarised in Tab. 2.3.

Table 2.3.: Impurities created by the irradiation of other elements present in target solution, target coating $(\mathrm{H}, \mathrm{O}, \mathrm{Cl}, \mathrm{Nb})$

| Elements | Isotopes | Percentage of composition | $\left(\mathrm{p},{ }^{*}\right)$ reactions in the $0-18$ <br> MeV range |
| :---: | :---: | :---: | :---: |
| H | ${ }^{1} \mathrm{H}$ | 99.98 | - |
|  | ${ }^{2} \mathrm{H}$ | 0.02 | $(\mathrm{p}, \gamma)^{3} \mathrm{He} ;(\mathrm{p}, \mathrm{n}+\mathrm{p})^{1} \mathrm{H}$ |
| O | ${ }^{16} \mathrm{O}$ | 99.76 | $(\mathrm{p}, 2 \mathrm{n}+2 \mathrm{p})^{13} \mathrm{~N} ;(\mathrm{p}, \alpha)^{13} \mathrm{~N}$ |
|  | ${ }^{17} \mathrm{O}$ | 0.04 | $(\mathrm{p}, \gamma)^{18} \mathrm{~F} ;(\mathrm{p}, \mathrm{n})^{17} \mathrm{~F}$ |
|  | ${ }^{18} \mathrm{O}$ | 0.20 | $(\mathrm{p}, \alpha)^{15} \mathrm{~N} ;(\mathrm{p}, \mathrm{n})^{18} \mathrm{~F}$ |
| Cl | ${ }^{35} \mathrm{Cl}$ | 75.76 | - |
|  | ${ }^{37} \mathrm{Cl}$ | 24.24 | $(\mathrm{p}, \mathrm{n})^{37} \mathrm{Ar}$ |
| Nb | ${ }^{93} \mathrm{Nb}$ | 100 | $(\mathrm{p}, \mathrm{n}+\mathrm{p})^{9 \mathrm{~m} \mathrm{Nb}} ;(\mathrm{p}, \mathrm{n})^{93 \mathrm{~m}} \mathrm{Mo}$ <br> $;(\mathrm{p}, \mathrm{n}+\alpha)^{89 \mathrm{~m}} \mathrm{Zr} ;(\mathrm{p}, \mathrm{x})^{89} \mathrm{Zr} ;$ <br> $(\mathrm{p}, \mathrm{x})^{92 \mathrm{~m}} \mathrm{Nb}$ |

The information about the radioisotopes created and summarised in the previous tables, is of little use without knowing every reaction's excitation function. The excitation functions will provide the information on how much of each radioisotope is produced and in which energy range, therefore allowing a careful tunning of the energy range desired.

Moreover, when plotted, the excitation function's must be corrected to the isotopic abundance of the elements. This means that all cross section values for reactions from the same isotope are multiplied by the isotopic abundance, so that when analysing a plot, it is straightforward to estimate how much of each isotope is produced.

In Fig. 2.3 it is clear that natural zinc is not a good target material for the production of gallium-68. This is mainly due to the competing ( $\mathrm{p}, \mathrm{n}$ ) reactions from the other isotopes.

Figure 2.2.: Excitation functions of all the possible proton induced reactions in natural zinc $\left[\mathrm{ESZ}^{+} 81\right.$, Her97, $\mathrm{HSS}^{+} 03$, How58, KCQ99, $\left.\mathrm{SUB}^{+} 08, \mathrm{SBT}^{+} 98\right]$.

When using enriched zinc, the available enrichment is usually around $>99 \%$, so it's safe to consider that it's highly pure and that the only concern regarding impurities will have to do with reactions that occur with zinc-68 other than the ( $\mathrm{p}, \mathrm{n}$ ) reaction. In Fig. 2.3 it's clear that the biggest concern should be the ( $\mathrm{p}, 2 \mathrm{n}$ ) Ga- 67 since it overlaps with the ( $\mathrm{p}, \mathrm{n}$ ) Ga- 68 in the $12-18 \mathrm{MeV}$ range and so this means that ideally the beam's energy should only be around 12 MeV .

Figure 2.3.: Excitation functions of reactions that occur when using ${ }^{68} \mathrm{Zn}$. [How58, $\left.\mathrm{SKR}^{+} 09\right]$

Tab. 2.3 is of particular interest because these elements are always present in the target solution and around it (in the case of niobium) no matter if the solution is made
with natural zinc or enriched zinc. Therefore, the analysis of the reactions, products and respective cross sections is critical to determine the amount of impurities created. In Fig. 2.4 the plotted cross sections clearly show that some by-products will have a considerable excitation function while others can be ignored. The isotopes that have a greater probability of being produced are ${ }^{13} \mathrm{~N},{ }^{92 m} \mathrm{Nb}$ and ${ }^{89 m} \mathrm{Zr}$.

Figure 2.4.: Excitation functions of proton induced reactions in the elements present in the target solution other than zinc[ACG ${ }^{+} 62$, GM59, KF74, Bai73, Ca02, $\mathrm{MBB}^{+} 97$, Rol73, $\left.\mathrm{DHC}^{+} 09\right]$.

### 2.5. SRIM simulation

To calculate the energy loss and range of particles during the irradiation process, a Monte Carlo simulation is performed using SRIM software (see sec. 1.2.3.1).

To be thorough when doing this kind of simulation it's necessary to understand the path that the beam follows from the moment it's extracted to the moment its energy is totally lost inside the target medium. To do so, a review of the whole target assembly is required (see Fig. 2.5).

Figure 2.5.: Scheme of the target assembly (picture courtesy of ©IBA ).

The following items appear in the order that the beam crosses them:

- Prime collimator - this collimator tapers from 32 mm to 9.5 mm ;
- Second collimator - provides a 9.5 mm collimating channel up to the window holder;
- Vacuum side window - is a cicular disk with a $12.5 \mu m$ thickness made from titanium;
- Window holder - holds the two window foils and spreads the cooling helium flow over the window foils;
- Target window - is a disk made from niobium whose thickness must be established from the simulations.

Although the collimators play an essential part in narrowing the beam they don't contribute to its energy loss and therefore aren't included in the simulation in which the main concern is the range of the particles.

Figure 2.6.: Simulation of particles crossing the vacuum side window, the window holder, target side window and finally the target medium.

The target solution that was simulated consisted in a 1 to 1 mass proportion of zinc chloride and water.

To carry out the simulation the characteristics of the different layers must be inserted into the software. They are described in the following table:

| Layer | Material | Width | Atom Stoichiometry | Density / g.cm ${ }^{-3}$ |
| :---: | :---: | :---: | :---: | :---: |
| Vacuum Window | Titanium | $12.5 \mu \mathrm{~m}$ | 1 | 4.518 |
| Window Spacer | Helium | 8 mm | 1 | 0.0001787 |
| Target Window | Niobium | $125 \mu \mathrm{~m}$ | 1 | 8.570 |
| Target Medium | Hydrogen |  | 1.538 |  |
|  | Oxygen | 14.5 mm |  | 0.295063 |
|  | Zinc |  |  |  |
|  | Chlorine |  | 0.076540 |  |

Table 2.4.: Layers with their respective characteristics.

The density of the target solution was determined experimentally by preparing a zinc chloride solution with 5 g of zinc chloride and 5 ml of water. Since the density of zinc chloride is $2.901 \mathrm{~g} . \mathrm{cm}^{-3}$, the volume of 5 g is $1.72 \mathrm{~cm}^{3}$. Because the reaction is exotermic, it's expected that the total volume doesn't correspond to the simple addition of the two volumes. This was observed and the final volume was 6.5 ml instead of 6.72 ml from the simple addition. This in turn corresponds to a 1.53 g. $\mathrm{cm}^{-3}$ solution density.

The atom stoichiometry of the target solution was chosen to reflect the chosen mass proportion. It was determined by a simple calculation:

$$
\begin{aligned}
& n_{\mathrm{H}_{2}}=\frac{1 \mathrm{~g}}{18 \mathrm{~g} \cdot \mathrm{~mol}^{-1}} \times 6.022 \times 10^{23}=3.34 \times 10^{22} \\
& n_{\mathrm{ZnCl}_{2}}=4.42 \times 10^{21}
\end{aligned}
$$

The number of atoms from each element is then:

$$
\begin{aligned}
& n_{\mathrm{H}}=3.34 \times 10^{22} \times 2=6.68 \times 10^{22} \\
& n_{\mathrm{O}}=3.34 \times 10^{22} \\
& n_{\mathrm{Zn}}=4.42 \times 10^{21} \\
& n_{\mathrm{Cl}}=8.84 \times 10^{21}
\end{aligned}
$$

The sum of these quantities yields the total number of atoms in a 2 g solution, and the weighted average gives the stoichiometry of the solution.

The energy of the particles is also another parameter that requires input and was chosen to be 18 MeV since it is the energy of the protons available from the cyclotron at ICNAS.

The output of the simulation is a group of files that are divided into three columns: Depth of Interaction, Ionization by Ions per unit of length, Ionization by Recoils. The results showed that the ionization by recoils is always 4 to 5 orders of magnitude smaller than the ionization by ions, as expected, and therefore they weren't taken into account.

Figure 2.7.: Energy transmitted to ions per unit of length. The peak at 8 mm corresponds to the energy loss in the target window. The 8 mm to 11 mm range corresponds to energy lost inside the target solution.

By plotting and integrating the depth of interaction vs ionization (see Fig. 2.7), it's possible to determine the energy lost by the beam in every step of the calculation. The outgoing energies after crossing each layer are summarised in the following table:

Table 2.5.: Outgoing energy from beam after crossing each layer.

| Layer | Outgoing energy / MeV |
| :---: | :---: |
| Vacuum Window | 17.91 |
| Window Spacer (Helium Flow) | 17.88 |
| Target Window | 16.28 |
| Target Medium | 0 |

### 2.6. Thick Target Yield

To calculate the yields that can be expected from an irradiation as well as the yields expected in saturation conditions, the data from SRIM coupled with the cross section data from the EXFOR database was used and inputed into expression 1.3. The calculation was then performed in turn for each thin layer, considering the energy of the beam constant in these layers, and its respective cross section value. The final result from this calculation is the number of induced nuclear reactions in each thin layer. After summing all these reactions, the result is the total number of induced reactions by one "beam crossing". The calculations that were done in a spreadsheet format are presented in the appendix.
The values used for the calculation are:

- $d=8.375 \times 10^{4}{ }^{\circ}$;
- $N=\left(4.42 \times 10^{21}\right) \times 0.0382$ which corresponds to total number of atoms in the target layer multiplied by the percentage of zinc-68 atoms which are the effective targets;
- $\sigma$ was determined for each energy value by fitting a 7th degree polynomial curve to the excitation function values for the ( $\mathrm{p}, \mathrm{n}$ ) Ga-68 reaction;
- $n_{i}$ was chosen to be the number of incoming protons in a $1 \mu \mathrm{~A}$ beam $(6.241 \times$ $10^{12}$ protons).
By chosing the number of projectiles to be a current instead of a number of protons, the result is the number of induced reactions per unit of time:

$$
\begin{equation*}
\frac{n_{r}}{t}=\frac{n_{i}}{t} N d \sigma . \tag{2.1}
\end{equation*}
$$

By considering this time to be very small compared to the half-lives of the produced isotopes, the expression is equivalent to:

$$
\begin{equation*}
A_{0}=\lambda I N d \sigma . \tag{2.2}
\end{equation*}
$$

where $A_{0}$ is the induced activity, $\lambda$ is the decay constant for gallium-68 and I is incoming beam current in units of projectiles per second.

This calculation is summarised in the following graph (Fig. 2.8):

Figure 2.8.: Induced activity by a $1 \mu A$ beam by unit of depth.

The total activity for a certain irradiation time by a $1 \mu A$ beam is then given by the expression:

$$
\begin{equation*}
A=\int_{0}^{t} A_{0}\left(1-e^{-\lambda t^{\prime}}\right) d t^{\prime} \tag{2.3}
\end{equation*}
$$

where each value of $A_{0}$ is decay corrected depending on the time that has gone by after the reaction has been induced.

To calculate the saturation yield, one can use two methods: either do the calculation using equation 1.9 or use the calculations described above and chose $t \gg \tau_{1 / 2}$.

Both techniques give the same result: $404.34 \mathrm{MBq} / \mu A h(10.92 \mathrm{mCi})$ activity of gallium-68 (if the target were natural zinc, the activity would be 2.052 mCi since only $18.8 \%$ of the target would be zinc-68).

## 3. Results

In order to confirm the theoretical predictions made in the previous chapter and also to verify the viability of the practical implementation of the technique in a cyclotron, an experiment that consists in the preparation of a target solution, the irradiation of the solution and the extraction and measurement of the solution's activity, was planned and executed.
However, some of the beam and solution characteristics that were determined in the previous chapter were not implemented:

- the target solution was prepared using natural zinc chloride. This contradicts the conclusion that natural zinc chloride is not a good material for the production of gallium-68. There is, nontheless, an interest in using natural zinc as a target for testing purposes due to the fact that zinc-68 is a quite expensive material (circa $€ 800 / \mathrm{g}$ ) compared to natural zinc ( $€ 0.13 / \mathrm{g}$ ). The reason why it's still useful for testing purposes has to do with it's chemical qualities. Since they behave exactly the same way with respect to chemical properties, one can do a fair amount of testing, without the burden of cost even though the desired product won't be achieved.
- The ideal beam energy was determined to be 12 MeV . The energy used in the experiment was 18 MeV , which after being degraded by the target window drops down to 16.3 MeV . This is far from the ideal energy determined, but it has little impact on this experiment since that energy was intended to be used when trying to avoid the ( $\mathrm{p}, 2 \mathrm{n}$ ) Ga-67 reaction. In this experiment, there are far more competing reactions in all of the ( $\mathrm{p}, \mathrm{n}$ ) Ga-68 energy range and so using a 12 MeV beam would have no pratical results.

### 3.1. Procedure

The procedure for this experiment involves 3 different steps:

- Preparation;
- Irradiation;
- Measurement.

For the preparation step the method chosen to prepare a solution with an equal mass ratio consisted in weighing 5 g of $\mathrm{ZnCl}_{2}$ and dissolving it in 5 ml of ultra pure water.

To ensure that the $\mathrm{ZnCl}_{2}$ was completely dissolved and that the solution had no deposits, the beaker was then placed in a vortex mixer and controlled by visual inspection. If little amounts of $\mathrm{ZnCl}_{2}$ were still found in the beaker, the solution was heated to around $80^{\circ} \mathrm{C}$ for 10 minutes. This procedure was used in every trial and after these steps were performed, none of the solutions prepared had any solid residues.

The irradiation step involves three sub-steps: the injection of the solution into the target chamber, the irradiation itself and the extraction. Ideally the injection step should be an automated process and this is the case with well established isotope production such as fluorine-18 and carbon-11, but since this is an experiment in its early stages, the injection process is made manually by accessing the cyclotron bunker and injecting the solution into the target chamber with a syringe.

Following the injection, the next step involves determining the desired beam current. The limiting factor for the beam current is the pressure that builds up inside the target due to the energy that is deposited by the beam in the solution. The niobium target side window was tested in the following way: helium was inserted into the target chamber at a pressure of 4 bar to check for possible leaks. As there were none, natural water was then inserted into the target chamber and irradiated. By slowly raising the current, the pressure inside the target increased and finally reached 40 bars (the operational pressure in all other fluorine targets used in this cyclotron). This condition was the maintained to verify that the window can withstand the pressure for some minutes.

After turning the beam off, the solution is extracted from the cyclotron using an electronic mechanism to control the opening and closing of the target valves that had to be built in-house due to the fact that it is impossible to access the cyclotron bunker after the irradiation step and therefore making it impossible to extract the solution manually. The solution was then forwarded to a conical vial inside a hot cell through a dedicated teflon line. After insuring by visual inspection of the vial that the entire solution volume is transfered, the vial is then inserted into the dose calibrator.

The measurement step is performed in a dose calibrator that is set to measure gallium-68. Since there is no available way to store the detector's output data in a computer, the activity of the sample as a function of time was collected by filming the calibrator's screen for several hours (10h-40h). The data was then extracted in 2 min . steps and inserted into a computer file for analysis.

This procedure was adopted for every trial and the results are presented in the next section.

### 3.2. Results and Analysis

### 3.2.1. Trial 1

The irradiation was performed until reaching $1 \mu \mathrm{Ah}$, which is the integrated current. The integrated current is always used as a reference since it is very difficult to maintain a constant beam current and therefore it would be difficult to compare experiments results based on such instable parameters.
The data collected over a 10 h span was plotted and is presented in Fig. 3.1:

Figure 3.1.: Plot of fitted trial 1 data in a log/lin scale along with the decay curves of the expected isotopes.

The best fit (Fig. 3.1) to this data was achieved by using a 7 parameter equation with SigmaPlot 10.0 software:

$$
\begin{equation*}
f(x)=y_{0}+a \times \exp (-b \times x)+c \times \exp (-d \times x)+g \times \exp (-h \times x) \tag{3.1}
\end{equation*}
$$

The fit's parameters are summarised in the following table (Tab.3.1).
Table 3.1.: Fit parameters of trial 1 data.

| Parameter | Value |
| :---: | :---: |
| $y_{0}$ | $1.273 \times 10^{-1}$ |
| $a$ | 33.32 |
| $b$ | $6.847 \times 10^{-2}$ |
| $c$ | 2.504 |
| $d$ | $1.355 \times 10^{-2}$ |
| $g$ | $9.03 \times 10^{-1}$ |
| $h$ | $2.659 \times 10^{-3}$ |

Taking into account that 3.1 has a physical meaning that corresponds to a radioactive decay, then parameters $b, d$ and $h$ must be decay constants of the produced radioisotopes, and $a, c$ and $g$ must be the amounts produced after the beam is turned off. Since,

$$
\lambda=\frac{\ln (2)}{\tau_{1 / 2}}
$$

the corresponding half-lives are presented in Tab.3.2.

Table 3.2.: Half-lives of the produced radioisotopes.

| Parameter | $\tau_{1 / 2} / \mathrm{min}$ | Expected Radioisotope | Expected $\tau_{1 / 2} / \mathrm{mn}$ | Deviation <br> $/ \%$ |
| :---: | :---: | :---: | :---: | :---: |
| $b$ | 10.12 | ${ }^{13} \mathrm{~N}$ | 9.96 | 1.58 |
| $d$ | 51.15 | ${ }^{68} \mathrm{Ga}$ | 67.71 | 24.45 |
| $h$ | 260.67 | ${ }^{66} \mathrm{Ga}$ | 569.40 | 54.22 |

The main reason why the determined half-life for ${ }^{66} \mathrm{Ga}$ is so far off from the expected value seems to be tied to the measurement time ( 10 h ) which is very close to one half-life of ${ }^{66} \mathrm{Ga}$. This results in a poor fit and in a percentual deviation of $54 \%$ from the expected value. For the shorter half-life of ${ }^{68} \mathrm{Ga}$, although the deviation is still significant $(24.45 \%)$ it is somewhat better than that of ${ }^{66} \mathrm{Ga}$. As for ${ }^{13} \mathrm{~N}$, it is clear that there is a very good match between the determined half-life and the expected one.

From this trial it's possible to conclude that one of the most important factors to take into account in this experiment is that the measuring time is critical since there are isotopes with very long half-lives. For the following trials, one concluded that the measurement time should be at least 3 times longer than the half-life of the longest isotope expected, which in turn corresponds to a measurement time of $\sim 24$ h.

In this first trial, the amount created of each radioisotope wasn't a concern since the main priority was to test the procedure and to insure that the target could in fact withstand the built up pressure inside the target and that the extraction process was done without any major problem. Although the transfer from the target to the vial inside the hot cell eventually occured, the time it took was far longer than expected (20-25 min) compared to transfer times of $2-5 \mathrm{~min}$ in the case of the fluorine production. This effect wasn't thoroughly investigated but unusual behaviors in the transport properties and viscosity of zinc chloride aqueous solutions have been reported in the literature and may be related to this effect.[WMH $\left.{ }^{+} 84\right]$

### 3.2.2. Trial 2

Before starting the experiment, the target was thoroughly cleaned with ultra pure water and a cold test was performed to insure that all systems were functional. This cold test consisted in injecting the target solution into the target chamber and then immediately extracting it without irradiation. The transfer time was coherent with the usual transfer times for the production of fluorine and the solution showed no presence of impurities, making it clear that both target and transfer lines were clean. This procedure was adopted for the next experiments too.

The irradiation was performed for 30 min until reaching $1 \mu \mathrm{Ah}$.
The data in this trial was collected over a span of 23 h and presented as a plot in Fig. 3.2:

Figure 3.2.: Plot of trial 2 data.

Following the same type of analysis as done in trial 1, the data was fitted with a 7 parameter function and the determined values were:

| Parameters | Values |
| :---: | :---: |
| $y_{0}$ | $2.296 \times 10^{-2}$ |
| $a$ | 38.5 |
| $b$ | $6.092 \times 10^{-2}$ |
| $c$ | 4.229 |
| $d$ | $9.958 \times 10^{-3}$ |
| $g$ | 1.241 |
| $h$ | $1.486 \times 10^{-3}$ |

Table 3.3.: Fit parameters of trial 2 data.

These values yield the following half-lives:

Table 3.4.: Half-lives of the radioisotopes produced in trial 2.

| Parameter | $\tau_{1 / 2} / \mathrm{mn}$ | Expected <br> Radioiso- <br> tope | Expected <br> $\tau_{1 / 2} / \mathrm{mn}$ | Percentual <br> Deviation <br> $/ \%$ |
| :---: | :---: | :---: | :---: | :---: |
| $b$ | 11.37 | ${ }^{13} \mathrm{~N}$ | 9.96 | 12.4 |
| $d$ | 69.60 | ${ }^{68} \mathrm{Ga}$ | 67.71 | 2.7 |
| $h$ | 466.45 | ${ }^{66} \mathrm{Ga}$ | 569.40 | 18 |

It is clear from these results that a longer measurement time yields better fits and consequently lower deviations from the expected values.

### 3.2.3. Trial 3

In this trial higher beam currents were attempted and an unusual effect was observed: the beam current was set to $10 \mu \mathrm{~A}$ and the target pressure rose to gradually to 15 bars and stabilized. The beam current was then increased to $25 \mu \mathrm{~A}$ and the target pressure rose to 20 bars and immediately returned to 15 bars and once again stabilized. The beam current was then reduced to $5 \mu \mathrm{~A}$ and the pressure dropped 6 bar and gradually rose to 15 bar once again, therefore suggesting that some sort of thermal equilibrium is reached inside the target and that deviations in beam current may result in the same pressure inside the target. Under these conditions, a higher integrated current was reached with the same irradiation time ( $\sim 30 \mathrm{~min}$ ) used in the previous trials.

The target was irradiated for 30 min until $6 \mu \mathrm{Ah}$ were reached.
The plot of the data along with the fit:

Figure 3.3.: Plotted trial 3 data along with fit.

Following the same type of analysis as done in trial 1, the data was fitted with a 7 parameter function and the determined values were:

Table 3.5.: Fit parameters of trial 3 data.

| Parameters | Values |
| :---: | :---: |
| $y_{0}$ | $2.741 \times 10^{-2}$ |
| $a$ | 349.2 |
| $b$ | $6.645 \times 10^{-2}$ |
| $c$ | 12.27 |
| $d$ | $1.042 \times 10^{-2}$ |
| $g$ | 2.090 |
| $h$ | $1.256 \times 10^{-3}$ |

The determined half-lives were:

Table 3.6.: Determined half-lives of the radioisotopes produced in trial 3.

| Parameter | $\tau_{1 / 2} / \mathrm{mn}$ | Expected Radioisotope | Expected $\tau_{1 / 2} /$ <br> mn | Percentual <br> Deviation $/ \%$ |
| :---: | :---: | :---: | :---: | :---: |
| $b$ | 10.43 | ${ }^{13} \mathrm{~N}$ | 9.96 | 4.5 |
| $d$ | 66.52 | ${ }^{68} \mathrm{Ga}$ | 67.71 | 1.78 |
| $h$ | 551.86 | ${ }^{66} \mathrm{Ga}$ | 569.40 | 3.17 |

In this trial, the fit indicates that at beam stop the amount of gallium-68 produced was 12.27 mCi . By using the calculation methods outlined in chapter 2 the predicted value for an irradiation of $6 \mu A h$ in a target with natural zinc is 12.32 mCi which reveals a very good accordance. If the target were to be composed by enriched zinc, this value would be 65.56 mCi .

Two days after finishing the measurement, a few drops of the solution were analysed in an MCA. This was done as a further proof of the production of all the predicted radioisotopes, and one that is difficult to observe using the method used previously is gallium- 67 since it has a 3 day half-life. But since gallium- 67 decays by gamma emission and not $\beta^{+}$like the other gallium isotopes, one expected to observe at least three peaks corresponding to the three gamma energies with the largest decay channels ( $97 \mathrm{keV}, 184 \mathrm{keV}$ and 300 keV with respectively $40 \%, 20 \%$ and $17 \%$ relative intensity).

After measuring for 60 seconds, the resulting spectrum follows in Fig. 3.4:

Figure 3.4.: Spectrum obtained after analysing sample in an MCA.

Although the peaks are not centered with the expected energies due to a possible miscalibration of the MCA, they belong unmistakably to gallium- 67 decays due to their relative intensities and spacing.

It is necessary to take into account that there is an inherent error in the measurement of the dose calibrator that can have some impact on the measurement of the half-lives of the isotopes. This error is usually proportional to the number of counts (these radiation detectors normally follow a Poisson statistic where the error is $\sqrt{\text { counts }})$.

The analysis of the data from each trial allowed for a constant optimization of the experimental techniques that culminate with the results of trial 3, where 12.27 mCi of gallium-68 were produced.

## 4. Conclusions and Future Work

From the several experiments performed it's possible to conclude that the production of gallium-68 in a cyclotron with a liquid target is possible and that it may yield quantities that can be used for the synthesis of radiopharmaceuticals. A solid target assembly yields unquestionably higher amounts of gallium-68, with values of 5 Ci at end of bombardement being reported in the literature ([SKR $\left.{ }^{+} 09\right]$ ) using a 15 mn irradiation time and $150 \mu \mathrm{~A}$ beam current. A gallium- 68 generator when eluted yields 35 mCi . This work has shown that if using an enriched zinc chloride solution, under the experimental conditions used, it is possible to obtain 65 mCi . There are several factors that may improve this production yield: a solution with a higher concentration of zinc chloride, higher irradiation time in order to approach a saturation condition ( $\sim 2 \mathrm{~h} \longrightarrow 75 \%$ saturation yield).
It is also important to stress that the irradiations were performed in a target originally intended to produce fluorine. The optimization of the target depth, cooling, shape, materials are all very important factors that may contribute to even further improvement of the production capabilities. One of the most relevant improvements that should be investigated is the possibility of integrating a beam degrader into the target assembly so that the beam's energy can be lowered to more optimal energies that would avoid producing ${ }^{67} \mathrm{Ga}$ through the competing reaction ( $\mathrm{p}, 2 \mathrm{n}$ ).
From the data analysis it is clear that gallium-68 was produced along with the other predicted isotopes and that throughout the progression of the experiment, the growing understanding of the procedure and of the behaviour of the solution during irradiation allowed for the optimization of the entire experiment. This in turn can begin to be seen as a draft of what a full protocol for the possible production of gallium-68 to be used in patients.
Moreover, the data obtained from the experiment is in good agreement with the calculations made in chapter 2. The observation of the isotopic impurities created alongside the gallium-68 demonstrate that the nuclear reactions that occur inside the target chamber during the irradiation are in fact the ones expected.
Although this work can be seen as a proof of principle of a new production method, the complete demonstration of the technique can only be shown by irradiating a target solution with enriched zinc- 68 which was shown to be the ideal target material. The study of the resulting yields and complete study of the chemical processes needed to separate the gallium from the solution and to recover the zinc-68 so that it can be used to perform further irradiations is a critical part of the entire production process.

Furthermore, though this work aimed in part at finding the most suitable chemical compound for the target material, it may be interesting to study this further and to find other compounds that behave in a more controlled manner so that some of the effects observed, like the increased transfer times and the pressure inside the target, can have less of an impact.

## B. SRIM outputs and calculations

## B.1. Beam degradation vs depth

The data presented here is the result of the SRIM simulation from chapter 2. With the resulting data, the beam's energy degradation was calculated for every step; using a polynomial fit of the reaction's cross section, the corresponding value of $\sigma$ was also determined for every step of the calculation.

With respect to the polynomial fit of the $\mathrm{Zn}-68(\mathrm{p}, \mathrm{n}) \mathrm{Ga}-68$, the equation used was $f(x)=a \times x+b \times x^{2}+c \times x^{3}+d \times x^{4}+g \times x^{5}+h \times x^{6}+i \times x^{7}$ and the determined fit parameters were:

Table B.1.: Fit parametres for the $\mathrm{Zn}-68(\mathrm{p}, \mathrm{n}) \mathrm{Ga}-68$ cross section.

| Parameter | Value |
| :---: | :---: |
| a | -640.416 |
| b | 392.701 |
| c | -94.3364 |
| d | 12.1984 |
| g | -0.865649 |
| h | 0.0313612 |
| i | -0.000452177 |

The fit and the cross section data was plotted:

Figure B.1.: Plot of the cross section data and the fit.

The last column shows the calculation of the thick target yield by considering the yield from each thin layer and summing it to the previous one. The thick target yield is the last value in the column.

The different colors represent different parts of the beam's path: in blue the vacuum side window and the helium flow from the window cooling, in yellow the target side window, and in green the target solution.
