Abstract

Background: Asthma and rhinitis have a complex etiology, depending on multiple genetic and environmental risk factors. An increasing number of susceptibility genes are currently being identified, but the majority of reported associations have not been consistently replicated across populations of different genetic backgrounds.

Purpose: To evaluate whether polymorphisms of IL4R (rs1805015), IL13 (rs20541), IL17A (rs2275913) and GSTP1 (rs1695) genes are associated with rhinitis and/or asthma in adults of Portuguese ancestry.

Methods: 192 unrelated healthy individuals and 232 patients, 83 with rhinitis and 149 with asthma, were studied. All polymorphisms were detected by real time polymerase chain reaction (PCR) using TaqMan assays.

Results: Comparing to controls, significant association with asthma was observed for GSTP1 rs1695 AA genotype (odds ratio (OR) = 1.96; 95% CI = 1.18 to 3.25; p = 0.010). The association sustains for allergic asthma (OR = 2.17; 95% CI = 1.23 to 3.80; p = 0.007). IL13 rs20541 GG genotype was associated with less susceptibility to asthma (OR = 0.55, 95% CI = 0.33 to 0.94, p = 0.028). Among patients, IL17A rs2275913 AA genotype was less associated with asthma than with rhinitis (OR = 0.20; 95% CI of 0.07 to 0.56; p = 0.002). A similar association was found for IL13 rs20541 GG genotype (OR = 0.48; 95% CI of 0.25 to 0.93; p = 0.031). There were no significant differences in the distribution of allelic and genotypic frequencies between patients and controls for the IL4R polymorphism analyzed.

Introduction

Asthma and asthma-related disorders, such as sinusitis and rhinitis, are complex diseases with strong genetic and environmental components. Over the last decades their prevalence has been increasing worldwide, with a significant economic impact on health services.

Asthma is a common chronic inflammatory disease of the lower airways, characterized by reversible airflow obstruction, inflammation, persistent hyper-reactivity and airway remodeling. Rhinitis is an upper airways inflammatory disease, often associated with asthma and has been recognized as a risk factor for its development and severity.

Genetic contribution to these phenotypes may account for 50–60%, so dissecting genetic susceptible profiles may provide insight into the pathogenesis, allowing us to identify different sub-phenotypes and also contribute to finding new targeted therapies.

An increasing number of asthma susceptibility loci are continuously being identified, either by candidate gene studies or, more recently, by microarray-based whole genome approach, the genome-wide association (GWA) studies. Results are hampered by difficulties common to other complex diseases: inconsistent replication of results, functional association between identified loci and phenotype is not obvious, and most of all, allele penetrance is low and phenotype variance largely remains to be explained.

Most marker SNPs (single nucleotide polymorphisms) are localized in or near-by genes encoding proteins directly or indirectly involved in immunologic response. Recently, GWAs have revealed that different allergic diseases with common immunological physiopathology, also share susceptibility loci.

Interleukin-4 (IL4) mediates important pro-inflammatory functions in allergic phenotypes and has principle responsibility for the IgE isotype switch by B lymphocytes. IL4 is also involved in T helper type 2 (TH2) lymphocytes activation, induction of endothelium modifications, hyper-secretion of mucus and with lung remodeling in chronic asthma. IL4 action is mediated through activation of its receptor IL4R, a cell-surface heterodimeric complex.

Interleukin-13 (IL13) is one of the cytokines released by IL4 mediated Th2 induced cells and shares most of IL4 functions. IL13 production in the airway promotes the survival and migration of eosinophils, activation of macrophages, increased permeability and mucus production by airway epithelial cells and stimulates airways hyperresponsiveness. Huang et al. found that asthmatic and rhinitis patients submitted to allergen-challenge had a significant enhancement of IL13 gene expression at mRNA and protein levels in bronchoalveolar lavage samples compared with the saline-challenged control sites.

Interleukin-17A (IL17A) is the best studied member of IL17 family of cytokines. It is mainly produced by activated T cells. Signaling through activation NF-kappaB and mitogen-activated protein kinases, IL17A regulates local tissue inflammation inducing the expression of pro-inflammatory cytokines, neutrophil-recruiting chemokines, cyclooxygenase-2 (COX2) and nitric oxide (NO). IL17A may also modulate the activation and proliferation of B cells, thus enhancing IgE production and has been associated with airway hyperresponsiveness and remodeling.

SNPs from IL4, IL4R and IL13 genes are among the polymorphisms most frequently implicated in susceptibility to asthma, rhinitis and allergic phenotypes in general, with some of these SNPs being associated with increased serum IgE levels. Up to now few studies are available on the association with genetic polymorphisms of IL17A family members.

Reactive oxygen and nitrogen species, originated from air pollutants or released by inflammatory cells and stressed bronchial epithelia, are major contributors to asthma and asthma related phenotypes. Glutathione-S-transferases (GSTs) are enzymes involved in the cellular detoxification of free radicals. A missense SNP in Glutathione S-transferase P1 (GSTP1), rs1695 (p.Ile105Val), has been associated with differences in enzyme activity and susceptibility to environmental-induced diseases, including asthma, but results remain controversial.

Frequencies of DNA polymorphisms vary between populations of diverse ethnic origins, as their contributions to complex diseases, therefore, it is important to study different populations. In this study we evaluate the role of IL4R rs1805015, IL13 rs20541, IL17A rs2275913 and GSTP1 rs1695 in the susceptibility to asthma and rhinitis in an adult population of Portuguese ancestry.

Materials and methods

Clinical samples

This case–control study comprises 424 non related Caucasian Portuguese individuals, including 232 patients and 192 controls, randomly selected from a larger sample that answered a home inquiry about symptoms of asthma, rhinitis and sinusitis. Individuals willing to participate were than observed at the Immunology Department of Coimbra University Hospitals.
The patient population was subdivided into two groups, according to the clinical diagnosis, using ARIA (Allergic Rhinitis and its Impact On Asthma), GINA (Global Initiative for Asthma) and EP3OS (European Position Paper on Rhinosinusitis and Nasal Polyps 2007) criteria: one group including patients with rhinitis but no asthma and another group including patients with persistent asthma, which could also have rhinitis. As explained in “Results” section, patients with both rhinitis and asthma were grouped with those who only had asthma. Controls had no symptoms related to respiratory system and no history of any allergic disease. Other known inflammatory or chronic conditions, including cancer, were exclusion criteria for both patients and controls. A skin prick test for 17 different inhalant allergens, selected according to the recommendations of the GAZLEN (Global Asthma and Allergy European Network), was performed on all patients and those who had at least one positive result were considered allergic. The test was considered positive when wheal diameter was ≥3 mm and controls showed sufficient reaction. Participants were considered allergic only in the presence of both symptoms and a positive skin prick test. The local ethics committee approved the study and patients provided informed consent.

**Genotyping**

DNA was extracted from 5 ml of frozen peripheral blood by standard methods. Characterization of the four SNPs was achieved by real time polymerase chain reaction (PCR) using the TaqMan assays (Applied Biosystems), iQTM Supermix (Bio-Rad Laboratories) and 10–30 ng of DNA, in a 7500 Fast Real-Time PCR System (Applied Biosystems). As positive controls, we used samples previously genotyped by automatic sequencing in an AbiPrism 3130 Genetic Analyser using BD v1.1 (Applied Biosystems) and Sequencing Analysis Software v5.2. The description of the four SNPs, the primers used in sequencing and TaqMan assay references are depicted in Table 1.

**Statistical analysis**

Statistical analysis was developed using the IBM® program SPSS® (Statistical Package for Social Sciences) version 20. Fisher exact-test, χ² was applied to analyze the difference between the three groups. Logistic regression models were used to control for potential confounders and to evaluate the associations between the risk of disease and genetic polymorphisms. All odds ratios (ORs) with 95% confidence intervals (CI) were adjusted for age, sex and smoking habits and p < 0.05 was considered statistically significant. When comparing rhinitis and asthma patients, ORs were also adjusted for atopy.

**Results**

A preliminary analysis revealed that for distribution of SNP variants, smoking habits and atopy (positive skin prick test results), there were no statistically significant differences between patients associated asthma and rhinitis and patients only with asthma (Supplementary Table 1). For this reason, and because asthma is considered a more aggressive phenotype, the two groups were joined together, so patients were further on classified as having rhinitis or asthma, as described in Table 2. The cohort of 83 patients with rhinitis had a mean age of 48.50 years (SD = 15.17) and 63.9% females. The group of 149 asthmatic patients was younger, with a mean age of 39.32 years (SD = 14.04) and 66.4% were females. The control group had a mean age of 56.06 years (SD = 19.48) and 52.1% females. According to results of skin prick test, allergy was more frequent among asthmatic patients (78.5%; Table 2).

The Hardy–Weinberg equilibrium was verified for the four polymorphisms (p > 0.05). The frequency of GSTP1 rs1695 AA genotype was significantly higher in patients with asthma than in controls (49.0% vs. 33.9%; OR – 1.96, 95% CI – 1.18 to 3.25; p = 0.010) (Table 3). When only considering patients with allergic asthma (data not shown) results were similar (OR – 2.17, 95% CI – 1.23 to 3.80; p = 0.007). IL13 rs20541 GG genotype was significantly less prevalent in asthma cases (62.6%) than in controls (70.8%) (OR – 0.55, 95% CI – 0.33 to 0.94; p = 0.028) (Table 3).

Among patients, IL13 rs20541 GG genotype was less frequently associated with asthma than with rhinitis (OR – 0.48, 95% CI – 0.25 to 0.93; p = 0.031) (Table 4). The IL17A rs2275913 AA genotype was also significantly less frequent in asthmatic patients (5.4%) than in rhinitis patients (16.9%) (OR – 0.20, 95% CI – 0.07 to 0.56; p = 0.002) (Table 4).

For IL4 rs1805015, there were no significant differences in the distribution of allelic and genotypic frequencies

between patients and controls (Table 3) or between the two disease phenotypes (data not shown).

**Discussion**

In this work we evaluate the role of polymorphisms of four genes, *IL4R*, *IL13*, *IL17A*, and *GSTP1* in the susceptibility to two related phenotypes, asthma and rhinitis.

As expected, patients were mostly of female gender. In agreement with previous studies, our results suggest that most patients with asthma have allergen sensitization.

Comparing patients and controls, *GSTP1 rs1695 AA genotype conferred about twofold risk for developing asthma and allergic asthma. These results of a Portuguese population are in accordance with previous studies that have associated the A variant with a higher risk, or the G (Val) variant with a lower risk to develop asthma and allergic phenotypes. Yet a meta-analysis only suggested a possible, weak protective effect of the G (Val) allele. Like other authors, we found no evidence of a correlation between *GSTP1* SNP and rhinitis.

GSTs play important roles in airway antioxidant defenses and *GSTP1* enzyme contributes to more than 90% of GST-derived enzyme activity in human lung epithelium. The rs1695 SNP has been associated with differences in GSTP1 substrate affinities. A recent study showed that asthma patients who have homozygosity for A (Ile) allele

<sup>c</sup> AdjOR – Adjusted Odds Ratio for age, gender and smoking habits.
are more likely to be affected by air pollutants. These findings substantiate the functional relevance of the SNP, and support our results. Yet, we are aware that this genetic effect can be affected by environment-induced epigenetic modifications that influence gene expression and ultimately, the level of enzymatic activity. Epigenetic regulation is tissue-specific and may account for some of the differences in GSTP1 role between upper and lower airways.

For IL13 SNP, our results suggest that homozygosity for G allele, corresponding to arginine (Arg) variant, may decrease susceptibility to asthma. IL13 polymorphisms have repeatedly been associated with increased IgE serum levels, allergy and asthma. The association of rs20541 with allergic rhinitis was reported in a recent meta-analysis of an Asian population. IL13 rs20541 (CAG>CGG) results in the non-conservative replacement of a neutral glutamine (Gln) for a positively charged arginine (Arg) in the IL13 α helix of D domain, the region that is thought to interact with IL4Rα/IL13Rα1 heterodimers. The A allele has been associated with increased IL13 expression and a lower affinity for the IL13 receptor α2 chain (IL13Rα2), which is a decoy receptor that antagonizes inflammation and tissue remodeling. These observations point to a lower inflammatory activity of arginine variant (G allele) compared with glutamine (A allele), supporting the association with a decreased susceptibility to asthma.

In contrast to other studies, we could not confirm the same correlations for rhinitis. The difference in results may be explained by the fact that upper airways patency is largely influenced by vascular tone, whereas in the lower airways, smooth muscle function is determinant. IL13 was shown to directly interfere with airway smooth muscle cell responsiveness by enhancing agonist-induced contractility and calcium signals, a mechanism that may be mediated by stromal interaction molecule-1 (STIM1), a sarcoplasmic reticulum protein involved in the regulation of intracellular Ca^2+ concentrations.

Comparing both groups of patients, IL17A rs2275913 AA genotype was less frequently associated with asthma than with rhinitis, reinforcing the difference between the genetic profiles of these phenotypes. This SNP is located in 5′ regulatory region, within a binding motif for the nuclear factor of activated T cells (NFAT), which is a critical regulator of the IL17A promoter. Peripheral blood level determination and gene reporter assays showed that the A variant was associated with increased levels of IL17A expression and displayed a higher affinity for NFAT.

For rhinitis, our data concur with the functional relevance of A variant. IL17A is known to be a proinflammatory, leukocyte-derived cytokine that targets epithelial cells and that seems to play a central role in rhinitis. IL17A expression in the nasal mucosa was associated with the pathophysiology of allergic rhinitis, including disease severity and local eosinophilia.

In asthma, increased expression of IL17A has been described mainly in severe and non-allergic forms. The majority of patients included in our study had moderate asthma, which may account for the negative association observed with the higher inflammatory activity A allele. Reinforcing our results, Lei et al. describe similar serum levels of IL-17A between asthmatic and normal controls. Globally, controversial results have been published, with studies suggesting that different polymorphisms of IL17A and IL17F may contribute both to susceptibility or resistance to asthma or allergic rhinitis.

No significant association was observed between IL4R rs1805015 polymorphism with rhinitis or asthma. Although this association was confirmed in recent GWA studies, contradictory reports exist and results frequently differ between populations.

The difference in results between our data and some previous reports is a common issue in complex disease research. Differences in population genetic backgrounds, in sample size and selection, phenotype classification, in environmental exposure and epigenetic mechanisms, contribute to the results divergence.

To overcome limitations of this study, in future work it will be important to enlarge the population samples to be analyzed and to define more specific and homogeneous phenotypes.

### Conclusions

We describe the existence of a significant association between GSTP1 rs1695 and IL13 rs20541 polymorphisms, respectively with higher and reduced susceptibility to
asthma. For patients that develop reactive inflammatory respiratory diseases, IL17A rs2275913 and IL13 rs20541 polymorphisms influence the predominant upper airways (rhinitis) or lower airways (asthma) clinical pattern. These results also support the hypothesis that the genetic susceptibility profiles of asthma and isolate chronic rhinitis are not equivalent.
