Active commuting and its associations with cardiovascular risk markers in children

Background: The positive impacts of active travel on cardiovascular health still require further research in youth populations which are increasing the risk of obesity. Purpose: The present study aimed to analyse the associations between active travel (e.g. walking/bicycling) to school and cardiovascular risk markers in children. Methods: The sample comprised 665 children (345 boys) aged 7-9 years. Height, weight, and skinfolds were collected by a trained fieldworker as well as data on cardiovascular risk markers between March 2009 and January 2010 (analysed data in 2012-2013). Information on mode and duration of travel to school was gathered by questionnaire. Outcome variables were statistically normalized and expressed as Z scores. Logistic regressions, with adjustments for confounders, were used. Results: Children who walking/bicycling to school were significantly less likely to have lower clustered CRS than their passive commuting counterparts. The final regression model also indicated that those walking or bicycling to school were more likely to have higher levels of PA than those who usually travel by motor transports; level of education of parents was also positive associated with active commuting in children. Conclusion: Findings showed an independent association between active commuting and the clustered of cardiovascular risk in children aged 7-9 yrs.

Dear Professor Franco,

After have been acting several times as reviewer for Preventive Medicine, our research group is pleased to submit the manuscript “Active commuting and its associations with cardiovascular risk markers in children” as a brief report for publication in the Preventive Medicine.

The manuscript is original, has been submitted solely to Preventive Medicine and it has not been previously published. The paper does not include content that is abusive, defamatory, libelous, obscene, and fraudulent, in violation of applicable laws, or which would otherwise be offensive.

All of the co-authors agree with the order of names on the title page of the manuscript and they have reviewed and approved the complete manuscript. The corresponding author would like to confirm full access to all aspects of the research and writing process, and take final responsibility for the paper.

Yours sincerely,

Aristides M. Machado-Rodrigues

ACTIVE COMMUTING AND ITS ASSOCIATIONS WITH CARDIOVASCULAR RISK MARKERS IN CHILDREN

ABSTRACT

Background: The positive impacts of active travel on cardiovascular health are well established in adults but still require further research, especially in youth populations which are increasing the risk of obesity. Purpose: The present study aimed to analyse the associations between active travel (e.g. walking/bicycling) to school and cardiovascular risk markers in children. Methods: The sample comprised 665 children (345 boys) aged 7-9 years. Height, weight, and skinfolds were collected by a trained fieldworker as well as data on cardiovascular risk markers (resting heart rate, diastolic and systolic blood pressure) between March 2009 and January 2010 (data were analysed in 2012-2013). Information on mode and duration of travel to school was gathered by questionnaire. Outcome variables were statistically normalized and expressed as Z scores. A cardiovascular risk score (CRS) was computed as the mean of the Z scores. Logistic regressions, with adjustments for confounders, were used. Results: Children who walking/bicycling to school were significantly less likely to have lower clustered CRS than their passive commuting counterparts. The final regression model also indicated that those walking or bicycling to school were more likely to have higher levels of PA than those who usually travel by motor transports; level of education of parents was also positive associated with active commuting in children. Conclusion: Findings showed an independent association between active commuting and the clustered of cardiovascular risk in children aged 7-9 yrs. These findings may be useful for policy makers and city planners when designing neighborhoods that promote PA.

Keywords: Inactivity, Childhood, Obesity, Public Health, Active transportation
INTRODUCTION

Active commuting, which usually means walking or cycling to school/work, could have multiple health benefits by increasing physical activity (PA) and reducing the adverse health effects of sedentary behavior caused, among other things, for motor vehicle transport (1).

Among youth, rates of active commuting to school have decreased beside a context of declining levels of PA and increasing prevalence of overweight (2, 3), which suggests that these trends are probably linked. The literature indicates that possible health benefits of active commuting to school include higher rates of PA and higher cardiovascular fitness among youth, which are linked with reduced risk for metabolic and cardiovascular diseases (4).

In context of the preceding trends, further research is needed since an increasing risk of obesity and metabolic problems in Southern countries of Europe is evident and where data is lacking. Therefore, this study aimed to analyse the associations between active travel (e.g. walking/bicycling) to school and cardiovascular risk markers in children.

METHODS

Sample

The Portuguese Prevalence Study of Obesity in Childhood (PPSOC) was a random cross-sectional survey conducted between March 2009 and January 2010 (data were analysed in 2012-2013). Details on sampling and response rates can be found elsewhere (5). A total of 17,509 2-13 year old children were recruited among whom 665 children (345 boys) aged 7-9 years were included in the present analyses. Ethical approval for PPSOC was given by the Portuguese Commission for Data Protection which requires anonymity and non-transmissibility of data (IRB). Curricular and parental informed consent was obtained prior to data collection.

Anthropometry
Height and weight were measured at school in the morning with participants in t-shirt and shorts and without shoes. Skinfold thicknesses (mm) (triceps, subscapular and suprailiac) were also measured by a trained research workers using a skinfolds caliper produced by Holtain Ltd, Crymych UK. Body mass index (BMI, kg/m²) was subsequently calculated.

**Physical Activity (PA)**

PA was assessed by a questionnaire, filled out by parents who collected information of PA [i.e. outside school, in organized sports, and mode and duration of travel to/from school (walking or cycling)]. These three PA variables were converted into the same units (minutes per week) and summed into one total PA variable. Similar procedure and variables were used in recent epidemiological studies (5); in addition, similar PA instrument was previously used in Portuguese youth with good reliability (ICC: 0.92 to 0.96) (6).

**Cardiovascular risk score (CRS)**

Diastolic (DBP) and systolic (SBP) blood pressure (mmHg), and resting heart rate (RHR) (beats/minute) were measured using an Omron M7 blood pressure monitor by trained research workers. Three measurements were taken for DBP, SBP and RHR, the mean of the three measurements were used in analyses. A clustered cardiovascular risk score was calculated from the above risk markers; similar procedure was used in previous epidemiological studies (7).

**Parental education**: Educational background of fathers and mothers was based on the Portuguese Educational System and the three educational levels were defined as: 1=Low-Education; 2=Middle-Education and 3=High-Education. Similar procedures have used in the Portuguese context (8, 9).
Statistical analysis

Sex-specific descriptive statistics were calculated for anthropometrical, daily PA and cardiovascular risk variables. One-way analysis of variance (ANOVA) was used to test the effect of sex on the above mentioned variables. All ANOVAs were followed with Bonferroni-corrected post hoc tests.

Associations between active commuting and the CVR, controlling for potentially confounding effects of chronological age, BMI, time spent in organized sports and, father and mother education were estimated using logistic regression analysis. The complex samples generalised linear models (CSGLM) procedure to produce results with robust standard errors that take into account clustering of participants by school were used. Significance was set at 5%. SPSS 15.0 (SPSS Inc., Chicago, Illinois, USA) was used.

RESULTS

Characteristics of the sample are summarized in Table 1. Time spent playing sport was, on average, significantly higher in males, whereas diastolic blood pressure and cardiovascular risk score were higher in females.

Children who walking/bicycling to school were significantly less likely to have lower clustered CVR than their passive commuting counterparts, after adjustment for confounders. The final regression model also indicated that those walking/bicycling to school were significantly more likely to have higher levels of PA than those who usually travel by motor transports; in addition, significant predictors of the active commuting were higher educational
level of fathers (odds ratio: 2.56, 95% CI 1.35 to 4.87, p<0.01) and mothers (odds ratio: 1.89, 95% CI 1.03 to 3.47, p<0.05).

[Table 2]

DISCUSSION

Understanding daily routine activities, such as active commuting, which may have important health implications in children should be analyzed, especially in under studied populations of Southern of Europe where the highest rates of obesity are prevalent. Data revealed that active commuting children were significantly less likely to have lower clustered CVR than their passive commuting counterparts. These results are consistent with previous research in U.S. (10), the Netherlands (11), Australia (12) and Portugal (13) which suggested that active commuters have higher odds to have a better cardiovascular and metabolic profile than their non-active peers, independent of moderate-to-vigorous physical activity (MVPA).

Physical environmental factors that may influence children’s mode of transport to school include road and sidewalk infrastructure, traffic safety, accessibility of public transportation, and weather conditions (14). Findings also revealed a positive association between active commuting and PA levels in youth corroborating previous studies (3, 10).

Data from these studies indicate that children who use active forms of transport to school accumulate approximately 20 additional minutes of MVPA per day on weekdays (3, 10) and expend 33.2 to 44.2 kcal more per day than do youth who are driven to school (15).

In the final model, the strongest predictor of active commuting among Portuguese adolescent girls was parental education. It has been suggested that mothers with higher levels of education are more likely to engage in health promoting behaviours and thus present an
influential role model for children (16). In fact, family characteristics, especially parents, may
play an important behavioural role, serving as models from early childhood through
adolescent years (17). However, the literature on the issue of SES and active commuting is
somewhat inconclusive. Some studies showed no association between family SES and
children’s mode of transport to school (18) while others showed a contrasting results in
Australia (19) and U.S. (20) suggesting that children from low SES backgrounds are more
likely than children from high SES backgrounds to actively commute to school, and may
require additional research.

Limitations of the present study should be also recognized; firstly, this study has a
cross-sectional design and, therefore, it is not possible to infer casual relationships.
Furthermore, habitual PA was obtained by self-reported instrument (e.g. parental proxy),
which might be inaccurate as parents are not always with their children, especially outside the
domestic environment. Other limitations include the absence of blood variables, such as lipids
and indicators of glucose metabolism that would allow more comprehensive examination.

CONCLUSION
The present study showed an independent association between active commuting and the
clustered of cardiovascular risk in children aged 7-9 years. Level of education of parents was
associated with active commuting in children. Both educational and environmental strategies
are necessary to encourage children to walk/bike and to provide safety and pleasant physical
environments for youth.
