Abstract

Repeated abuse of stimulant drugs, cocaine and amphetamine, is associated with extraneuronal dopamine accumulation in specific brain areas. Dopamine may be cytotoxic through the generation of reactive oxygen species, namely hydrogen peroxide (H2O2), resulting from dopamine oxidative metabolism. In this work, we studied the cytotoxicity in PC12 cells (a dopaminergic neuronal model) chronically and/or acutely exposed to cocaine or amphetamine, as compared to H2O2 exposure. Chronic cocaine treatment induced sensitization to acute cocaine insult and increased cocaine-evoked accumulation of extracellular dopamine, although no changes in dihydroxyphenylacetic acid (DOPAC) levels were observed. Moreover, dopamine was depleted in cells chronically exposed to amphetamine and acute amphetamine toxicity persisted in these cells, indicating that dopamine was not involved in amphetamine cytotoxicity. PC12 cells chronically treated with H2O2 were totally resistant to acute H2O2, but not to acute cocaine or amphetamine exposure, suggesting that the toxicity induced by these stimulant drugs is unrelated to adaptation to oxidative stress. Interestingly, chronic cocaine treatment largely, but not completely, protected the cells against a H2O2 challenge, whilst a decrement in intracellular ATP was observed. This study shows that chronic treatment of PC12 cells with cocaine or H2O2 modifies the cytotoxic response to an acute exposure to these agents.

Keywords: Amphetamine; Cocaine; Drug abuse; Neurotoxicity; Oxidative stress

1. Introduction

The continuous abuse of drugs is sustained by the activation of the reward circuits in the brain, which is mainly associated with changes in dopaminergic activity (Di Chiara and Imperato, 1988). The stimulant drugs amphetamine and cocaine are known to increase extraneuronal dopamine levels through different mechanisms. Amphetamine can redistribute the dopamine stored in vesicles to the cytoplasm (Sulzer et al., 1995), inducing non-vesicular release of dopamine, which is mediated by the plasma membrane dopamine transporter (DAT, Kahlig et al., 2005). On the other hand, cocaine inhibits DAT (Brown et al., 2001), preventing the reuptake of dopamine to the nerve terminal, thereby increasing the levels of dopamine in the synaptic cleft.
One of the mechanisms of removal of dopamine from the extraneuronal space is via its metabolism, which may involve oxidation by monoamine oxidase (MAO), or its auto-oxidation. Both these mechanisms involve the generation of hydrogen peroxide (H$_2$O$_2$), which may react with transition metal ions, via the Fenton-Haber Weiss reaction, originating the highly toxic hydroxyl radical (•OH). Thus, altered dopamine metabolism induces oxidative stress and cell death in dopaminergic cells (Jones et al., 2000).

Reactive oxygen species have been frequently associated with neuronal cell death due to the oxidation of carbohydrates, amino acids, phospholipids and nucleic acids (reviewed by Cadet and Brannock, 1998). Accordingly, acute exposure to H$_2$O$_2$ has been reported to induce apoptotic cell death in PC12 cells (Benedi et al., 2004; Jang and Surh, 2004). In contrast, cells chronically exposed to low concentrations of H$_2$O$_2$ become resistant to H$_2$O$_2$-induced toxicity (Wiese et al., 1995; Davies, 1999). Thus, acute H$_2$O$_2$ can be used as a model of cytotoxicity, whereas chronic treatment of PC12 cells with H$_2$O$_2$ is a model of cellular adaptation (Jackson et al., 1994).

Chronic exposure to the drugs of abuse in humans induces long-lasting changes in gene expression, and some of these changes may be correlated with the development of the compulsive behaviour associated with drug addiction (Rhodes and Crabbe, 2005, for review). Changes in gene expression induced by chronic drug exposure may underlie changes in the cellular responses to stress. These alterations are also in the basis for the development of sensitization or tolerance, in human drug abusers, in which the response to the same dose of a drug is increased or decreased, respectively. These processes contribute to the withdrawal symptoms and to increased motivation to drug abuse (Nestler, 2004). Thus, we hypothesise that chronic drug exposure may also be involved in altered responses to cytotoxic insults, such as an acute exposure to the same drug or to other cytotoxic stimuli, such as oxidative stress.

Taking this into account, we analysed the effect of chronic exposure of PC12 cells to non-toxic concentrations of cocaine, amphetamine or H$_2$O$_2$, as compared to PC12 cells non-exposed to the drugs of abuse (naive cells). The cells were further treated with toxic concentrations of cocaine, amphetamine or H$_2$O$_2$ (acute exposure), based on our previous studies with PC12 cells chronically exposed to cocaine, amphetamine or H$_2$O$_2$. In particular, increased toxicity of cocaine in cells chronically exposed to this stimulant drug may contribute to the behavioural sensitization of drug addicts after acute cocaine exposure.

2. Material and methods

2.1. Materials

Cocaine was obtained from the “Instituto da Droga e da Toxicidade” (IDT, Lisbon, Portugal). Amphetamine, May-Grünewald and Giemsa solutions were obtained from Merck (Darmstadt, Germany). PC12 cells were obtained from ATCC (Manassas, VA, USA). RPMI and MTT were purchased from Sigma Chemical Co (St. Louis, MO, USA).

2.2. Culture and treatment of PC12 Cells

PC12 cells were cultured in 75 cm$^2$ flasks, in RPMI 1640 medium supplemented with 10% (v/v) horse serum, 50 U/mL penicillin, and 50 mg/mL streptomycin. Cultures were maintained at 37°C in a humidified incubator containing 95% air and 5% CO$_2$. The cells were plated on poly-l-lysine coated multiwells at a density of 50,000 cells/cm$^2$ for MTT studies and 160,000 cells/cm$^2$ for HPLC analysis.

For chronic treatment, PC12 cells were cultured for 7–12 months in RPMI medium supplemented with non-toxic concentrations of cocaine (30 μM), amphetamine (30 μM) or H$_2$O$_2$ (10 μM). Toxicity studies revealed similar responses in cells chronically exposed to the drugs or H$_2$O$_2$ from 7 to 12 months (data not shown). For acute treatment, the cells were exposed to toxic concentrations of cocaine (3 mM), amphetamine (1 mM) or H$_2$O$_2$ (50–75 μM), for 24–96 h. Concentrations of the stimulant drugs (Oliveira et al., 2002) or H$_2$O$_2$ (data not shown) for chronic or acute experiments were previously established in PC12 cells.

2.3. Assessment of cell viability

Cell viability was measured using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assay at 570 nm, as described previously (Oliveira et al., 2002). Briefly, the cells were incubated with 0.5 mg/ml MTT in Na$^+$ medium (in mM: 140 NaCl, 5 KCl, 1 MgCl$_2$, 1 Na$_2$HPO$_4$, 1.5 CaCl$_2$, 5.6 glucose, 20 HEPES, pH 7.4) for 24 h and the precipitated salt was dissolved with 0.04 M HCl in isopropanol. The capacity of treated cells to reduce the tetrazolium salt was expressed as a percentage of absorbance in control cells.

2.4. Measurement of dopamine and DOPAC levels

The intracellular levels of dopamine and dihydroxyphenylacetic acid (DOPAC) were determined after cell extraction with 0.1 M perchloric acid (0–4°C). The cells were centrifuged at 15,800 × g for 10 min, and the pellet was solubilized with 1 M NaOH for total protein analysis using the Sedmak method (Sedmak and Grossberg, 1977). The resulting supernatants,
stored at $-80\,^\circ C$, were extracted with alumina, using dihydroxybenzylamine (DHBA) as an internal standard, and assayed for dopamine and DOPAC analysis by HPLC with electrochemical detection, as described previously (Warnhoff, 1984). Dopamine accumulated in the cultured media upon acute exposure to cocaine or amphetamine, was determined using the same procedure.

2.5. Morphological analysis of PC12 cells

Cell morphology was evaluated by staining cell smears with May-Grünwald-Giemsa staining procedure. Naive cells and cells chronically exposed to the stimulant drugs or to $H_2O_2$ ($1 \times 10^5$ cells), before or after an acute exposure to $50\mu M H_2O_2$, were centrifuged at $200 \times g$ for 5 min, resuspended in $30 \mu l$ of FBS and placed on a slide for analysis at the microscope. Cell smears were stained with May-Grünwald and Giemsa solutions. Cell morphology was analysed by optical microscopy using a Leitz Dialux 20 microscope associated with a digital camera.

2.6. Measurement of intracellular ATP levels

Intracellular ATP was determined after cell extraction with 0.3 M perchloric acid (0–4 $^\circ C$). The cells were centrifuged at 15,800 $\times g$ for 10 min, and the pellet was solubilized with 1 M NaOH for total protein analysis using the Biorad protein assay (Biorad). The supernatants were neutralized with 3 M KOH in 1.5 M Tris, and centrifuged at 15,800 $\times g$ for 10 min. The resulting supernatants, stored at $-80\,^\circ C$, were assayed for ATP determination, by separation in a reverse-phase HPLC, as described previously (Rego et al., 1997).

2.7. Statistical analysis

Data are the mean $\pm$ S.E.M. from at least three experiments, performed in duplicate or triplicate. Statistical analysis was performed by the Student’s $t$-test (a $P < 0.05$ was considered significant).

3. Results

3.1. Chronic cocaine treatment sensitizes PC12 cells to acute cocaine

The toxicity of acute exposure to stimulant drugs was analyzed in naive PC12 cells and cells chronically exposed to cocaine, amphetamine or $H_2O_2$, by following the MTT reduction assay (Fig. 1). The effect of long-term exposure to cocaine, amphetamine or $H_2O_2$ on cell viability was not possible to assess using the MTT assay because cells chronically exposed to these agents revealed an increased capacity to reduce MTT (about two-fold), which can result from an increase in cell proliferation and/or an increase in cell viability. Exposure of dividing mammalian fibroblasts to low concentrations of oxidants ($3–15\mu M H_2O_2$) was previously reported to stimulate cell growth and proliferation (Davies, 1999). Thus, it is possible that the increase in MTT reduction observed in cells chronically exposed to $H_2O_2$ or to the stimulants is due to an increase in cell proliferation rather than a direct effect on cellular reduction systems or cell viability. Therefore, MTT reduction data were normalized as a percentage of control for each sub-cell line to evaluate the susceptibility induced by acute exposure to the agents, after different long-term pre-treatments.

Acute cocaine exposure ($3 \mu M$, for 96 h) decreased the viability of naive cells by about 40%, whereas in cells previously exposed to cocaine the decrement in cell viability was about 60%. Thus, chronic cocaine sensitized PC12 cells to acute cocaine toxicity by about 20%. In contrast, acute incubation with amphetamine ($1 \mu M$, for 96 h) induced the same decrease in cell viability (about 40%) in naive cells or in cells previously exposed to amphetamine (Fig. 1).

Since cocaine and amphetamine are known to interfere with the dopaminergic system, we evaluated the effects of chronic and acute exposure to these psychostimulants in the accumulation of extracellular dopamine.
Fig. 2. Dopamine and DOPAC levels upon an acute exposure to cocaine or amphetamine, of naïve cells or cells chronically exposed to cocaine (A, C and E) or amphetamine (B, D and F), for 7–12 months. The cells were acutely exposed to cocaine (3 mM) or amphetamine (1 mM), for 24 h. Intracellular dopamine levels (Fig. 2C and D) and the endogenous levels of its metabolite, DOPAC (Fig. 2E and F). Acute cocaine (3 mM) or amphetamine (1 mM) exposure for 24 h in naïve PC12 cells, increased extracellular dopamine accumulation, by about 7.6-fold and 5.6-fold, respectively (Fig. 2A and B). Concordantly, under these conditions, a decrease in intracellular dopamine levels was observed in the presence of cocaine (decreased by 3.5-fold) or amphetamine (decreased by 8.3-fold) (Fig. 2C and D). Moreover, acute amphetamine treatment largely decreased DOPAC levels, compared to the control, by 4.7-fold (Fig. 2F),
exposed to H_2O_2 the same acute exposure did not signif-
ificantly change cell viability, indicating that these cells chronically 
treated with the same drug, indicating that the extra 
dopamine was not metabolized by MAO (Fig. 2E).
These data suggested that cocaine sensitization in cells 
chronically exposed to cocaine (Fig. 1) was related with an increase in cocaine-evoked extracellular dopamine accumulation.

Interestingly, no detectable levels of extracellular or intracellular dopamine (Fig. 2B and D) or intracellu-
lar DOPAC (Fig. 2F) were observed in cells chronically 
exposed to amphetamine. Thus, amphetamine toxicity in 
cells chronically exposed to amphetamine (Fig. 1) cannot 
be attributed to changes in extracellular or intracellular dopamine. Amphetamine-induced depletion of endoge-
 nous dopamine can be explained by long-term inhibition of tyrosine hydroxylase, the rate-limiting enzyme in the 
synthesis of dopamine (Bowyer et al., 1998). On the 
other hand, amphetamine is also known to decrease DAT 
activity (Kahtig et al., 2004), decreasing the reuptake of 
released dopamine.

3.2. Cells chronically exposed to cocaine are partially resistant to H_2O_2

Repeated exposure to H_2O_2 is known to induce cel-
lular adaptation to acute H_2O_2 in PC12 cells (Jackson 
et al., 1994) and in other cell types (Wiese et al., 1995; 
Seong et al., 2002). In this study, we compared the toxi-
city of H_2O_2 in cells chronically exposed to the drugs of 
abuse or to H_2O_2. In naive cells, acute exposure to H_2O_2 
(75 μM, for 24 h) induced a decrease in cell viability by about 80% (Fig. 1). In contrast, in cells chronically 
exposed to H_2O_2, the same acute exposure did not signifi-
antly change cell viability, indicating that these cells are completely resistant to H_2O_2-induced toxicity and thus adapted to oxidative stress injury. Moreover, upon 
chronic exposure to H_2O_2, the toxicity of cocaine or amphetamine was similar to the toxicity observed in naive cells (Fig. 1), suggesting that toxic effects medi-
ated by the stimulant drugs were independent of adap-
tive changes induced by oxidative stress. Interestingly, 
cells chronically exposed to cocaine were more resis-
tant to acute H_2O_2 than naive cells, showing a decrease in cell viability by about 25% only (Fig. 1). In con-
trast, cells chronically exposed to amphetamine were 
only slightly more resistant to acute exposure to H_2O_2, (cell viability decreased by about 70%), in compar-
sion with naive cells. No significant changes in Bcl-
2/Bax were observed in PC12 cells chronically exposed 
to cocaine, amphetamine or H_2O_2 (data not shown), 
thus not explaining the different susceptibility of these 
cells.

Since chronic cocaine appeared to mediate some resistance to H_2O_2 toxicity (Fig. 1), we also analyzed 
the morphology of PC12 cells and the intracellular lev-
els of ATP upon an acute exposure to H_2O_2 in cells 
chronically treated with cocaine, which were compared 
to cells adapted to H_2O_2. Exposure of naïve cells to H_2O_2 
(50 μM, for 24 h) induced a decrease in cell viability by 
about 70% (data not shown), similar to 75 μM H_2O_2 
(Fig. 1). Under these conditions, the cells showed mem-
brane blebbing and cell shrinkage (Fig. 3A), indicating a 
some degree of lesion, compatible with the viability 
assay. In contrast, cells chronically exposed to H_2O_2 or 
to cocaine, showed a normal morphology after an acute 
abuse to H_2O_2 (Fig. 3A). These data were in accor-
dance with data shown in Fig. 1.

Acute exposure of naïve cells to H_2O_2 induced a decrease in intracellular ATP levels, by about 23%, 
whereas in cells chronically exposed to H_2O_2, ATP lev-
elts were maintained after an acute exposure to H_2O_2 
(Fig. 3B), indicating a complete adaptation to oxidative stress-mediated changes in energy metabolism. How-
ever, in cells chronically exposed to cocaine, ATP levels 
were decreased by about 28% after exposure to H_2O_2. 
Thus, although cells chronically exposed to cocaine were 
more resistant to H_2O_2, intracellular ATP levels were 
still affected, suggesting that this may account for the 
increased susceptibility of cells chronically treated with 
cocaine, compared to cells treated with H_2O_2, when sub-
mitted to an acute H_2O_2 challenge (Fig. 1). Endogenous 
levels of ADP were not significantly affected by acute 
exposure to H_2O_2 in naive cells or in cells chronically 
exposed to cocaine or H_2O_2 (data not shown), suggesting a decrease in ATP synthesis. The apparent lack of corre-
lation between the high toxicity of acute H_2O_2 (Fig. 1) 
and the moderate decrease in ATP levels (Fig. 3), under 
similar experimental conditions, can be explained by the 
normalization of ATP levels over the protein content, 
which is not taken into consideration in the MTT reduc-
tion assay.
Fig. 3. Effect of an acute exposure to H$_2$O$_2$ in cells chronically exposed to cocaine or H$_2$O$_2$. (A) Cell morphology: cell smears were stained following May-Grünwald staining procedure and photographed under 100× magnification in a Leitz Dialux 20 light microscope associated with a camera. Note the formation of blebs and cell shrinkage upon exposure of naïve cells to 50 μM H$_2$O$_2$ for 24h. Images are representative of three experiments performed in duplicate. (B) Intracellular ATP levels were detected by HPLC with UV detection, before or after incubation with 50 μM H$_2$O$_2$ for 24h. Data are the mean ± S.E.M. of four experiments performed in triplicate. Statistical significance: *P < 0.05 and **P < 0.01 compared to the control.

4. Discussion

4.1. Cocaine sensitization and dopamine toxicity

In this study, we showed that chronic cocaine increases the susceptibility of PC12 cells to acute cocaine toxicity, occurring concomitantly with enhanced cocaine-evoked dopamine release. PC12 cells chronically exposed to cocaine showed a non-statistical increase (by 2.2-fold) in intracellular dopamine levels, which could help to explain the increase in cocaine-evoked extracellular dopamine accumulation observed in Fig. 2A, since dopamine release induced by cocaine is dependent on the vesicular pool of the neurotransmitter (Pfi et al., 1995). Repeated cocaine administration has been described to increase tyrosine hydroxylase activity, the rate-limiting enzyme in the biosynthesis of dopamine, in brain areas affected by cocaine, such as the ventral tegmental area (Sorg et al., 1993) or the substantia nigra (Vrana et al., 1993). Since reuptake of dopamine is inhibited by cocaine (Brown et al., 2001), increased intracellular levels of dopamine could be due to increased dopamine biosynthesis. Furthermore, under control conditions, extracellular dopamine levels in cells chronically exposed to cocaine were not statistically different from those in naïve cells (Fig. 2A). This observation could be due to an increase in expression of plasma membrane DAT, as reported previously in cells subjected to low concentrations of cocaine (Kahlig and Galli, 2003, for review). Thus, dopamine uptake during chronic treatment with cocaine could be preserved. Dopamine has been described to be cytotoxic to PC12 cells, inducing oxidative stress and apoptosis (Wang et al., 2005), in a process occurring through activation of NF-κB (Panet et al., 2001) or the SAPK/JNK pathway (Luo et al., 1998). Nevertheless, no evidences of changes in dopamine metabolism by MAO were found, as examined by the maintenance of DOPAC levels in cells exposed to cocaine (Fig. 2E). Importantly, the observed increase in cocaine-evoked dopamine release may be related to the behavioral sensitization induced by this drug (Williams and Steketee, 2005), which is defined by increased motor activity after repeated administration.

4.2. Cocaine-induced partial resistance to H$_2$O$_2$ toxicity

Chronic cocaine treatment was shown to partially protect PC12 cells against H$_2$O$_2$-induced toxicity, despite the decrease in ATP (by ~28%), which reflects metabolic dysfunction. In contrast, chronic treatment with H$_2$O$_2$ completely prevented H$_2$O$_2$ acute toxicity, as evaluated by MTT reduction (Fig. 1), cell morphology (Fig. 3A) and ATP levels (Fig. 3B). Several mechanisms have been proposed to explain cellular adaptation to H$_2$O$_2$. Moderate concentrations of H$_2$O$_2$ (0.25 mM, for 24h) increase the capacity of oxidant degradation by antioxidative enzymes, whereas lower concentrations (0.05 mM, for 24h) block the signaling pathways triggered by toxic concentrations of H$_2$O$_2$ (1 mM) (Lee and Um, 1999). On
the other hand, $H_2O_2$ adaptation may involve increased translocation of NF-kB to the nucleus, which contributes to increased cell survival (Kim et al., 2001a), not involving an increase in Bcl-2 or Bcl-XL (Lee and Um, 1999). Another signaling pathway regulated by $H_2O_2$ is the SAPK/JNK pathway, which is activated by high concentrations of $H_2O_2$ and suppressed by low adaptive concentrations of $H_2O_2$ (Kim et al., 2001b). The interference with these signaling pathways may confer increased cell resistance to $H_2O_2$, without increasing the capacity of degrading $H_2O_2$ (Lee and Um, 1999). Moreover, $H_2O_2$ adaptation induces cross-resistance to serum withdrawal and C2-ceramide by blocking their ability to activate the SAPK/JNK pathway (Kim et al., 2001b). Acute $H_2O_2$ toxicity has been reported to involve the inhibition of ADP phosphorylation, namely through the inhibition of glyceraldehyde-3-phosphate dehydrogenase, in glycolysis, and the ATP synthase complex, at the mitochondrial respiratory chain (Hyslop et al., 1988). This could account for the decrease in intracellular ATP levels observed in naive PC12 cells and in cells chronically exposed to cocaine, following acute exposure to $H_2O_2$ (Fig. 3B).

Furthermore, proteomic analysis showed that adaptation to low concentrations of $H_2O_2$ may induce upregulation of proteins involved in energy metabolism, such as ATP synthase and glyceraldehyde-3-phosphate dehydrogenase (Seong et al., 2002), which may explain the maintenance of intracellular levels of ATP (Fig. 3B). In addition, proteomic analysis also suggests that upregulation of translation and RNA processing, chaperoning and redox regulation may also be in the basis for adaptation to $H_2O_2$ (Seong et al., 2002).

In cells chronically exposed to cocaine, $H_2O_2$ toxicity seemed to affect cell metabolism (Fig. 3B). Thus, the mechanism involved in the partial resistance of these cells to acute $H_2O_2$ is certainly not related to stimulation of energy metabolism. Similarly to $H_2O_2$, chronic cocaine was also reported to induce the activation of NF-kB (Ang et al., 2001) and AP-1 (Lee et al., 2001), two transcription factors described to be activated under oxidative stress conditions. Furthermore, repeated exposure to cocaine in rats was shown to increase the activity of glutathione peroxidase and superoxide dismutase, two antioxidant enzymes (Dietrich et al., 2005). Thus, the mechanism of partial resistance to $H_2O_2$ toxicity in cells chronically exposed to cocaine may possibly be explained by the activation of intracellular signaling pathways involved in the adaptation to $H_2O_2$, by low concentrations of cocaine. Nevertheless, high concentrations of cocaine induced toxicity in $H_2O_2$-treated cells, suggesting that toxic effects mediated by high concentrations of cocaine are unrelated to adaptive changes induced by oxidative stress.

4.3. Amphetamine-induced dopamine depletion and amphetamine toxicity

Chronic exposure to amphetamine-induced dopamine depletion (Fig. 2B and D). Nevertheless, acute amphetamine toxicity persisted in cells lacking dopamine (Fig. 1), indicating that dopamine is not involved in amphetamine toxicity. In vivo studies demonstrated that amphetamine toxicity is associated with a decrease in striatal dopamine levels (Wagner et al., 1980), decreased tyrosine hydroxylase activity (Ellison et al., 1978) and loss of dopamine transporter activity (Saunders et al., 2000). Although toxic mechanisms caused by amphetamine have been largely associated with the dopaminergic system, a more general mechanism of toxicity for amphetamine was also described, which involves disruption of the mitochondrial potential due to the net positive charge of amphetamine (Davidson et al., 2001). In accordance, we have previously observed that acute exposure of PC12 cells to amphetamine (1 mM, for 96h) resulted in a decrease in intracellular ATP/ADP ratio (Oliveira et al., 2002). Moreover, increasing evidences suggest that amphetamine, or amphetamine derivatives, can have toxic effects in non-dopaminergic cells, such as cerebellar granule cells exposed in vitro to 4 mM methamphetamine or methylenedioxy-methamphetamine (Jimenez et al., 2004) and rat medium spiny projection neurons in the striatum, upon in vivo exposure to four times 10 mg/kg p-amphetamine (Krasnova et al., 2005).

In conclusion, this study provides further data confirming functional alterations in dopaminergic cells chronically exposed to amphetamine or cocaine. We showed that chronic treatment with amphetamine induced dopamine depletion, which did not affect amphetamine or $H_2O_2$ cytotoxicity in these cells. Furthermore, exposure to cocaine increased the sensitivity to an acute cocaine exposure, along with cocaine-evoked extracellular dopamine accumulation, which may be related with increased motor activity after repeated administration of this drug of abuse (Williams and Steketee, 2005). Moreover, in contrast to prolonged exposure to $H_2O_2$, chronic cocaine induced a partial resistance to $H_2O_2$-mediated cytotoxicity, which was not correlated with the maintenance of energy levels. These data suggest that distinct cellular mechanisms operate during prolonged exposure to cocaine or $H_2O_2$, implicating major changes in cell susceptibility.
